INDEX TO VOLUME II., 1930.

REFERENCES AND ABBREVIATIONS

Readers in search of a given subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral, Heart and Cardiac, Liver and Hepatic, Child and Infant, Goitre and Thyroid, Diabetes, Glycosuria and Sugar, Eye, Ophthalmic, and Vision, Lunacy and Mental Disease, Arsenobenzol and Salvarsan, &c., &c., and that regional headings are more frequently used than pathological. Institutions and Corporations with the right to the prefix Royal will be found under that prefix, with the exception of Hospitals, which will be found under that heading; and Medical Societies, which are separately indexed under Societies. All Universities are indexed under the word University. (A.) = Annotation, (C.) = Correspondence, (N.I.) = New Inventions, (L.A.) = Leading Article, (M.L.) = Medico-legal, (M.T.T.) = Modern Technique in Treatment, (O.) = Obituary, (P.I.) = Parliamentary Intelligence, (R.) = Review, (R. and A.) = Reports and Analyses, (A.D.) = Clinical Interpretation of Aids to Diagnosis, (N.P.) = New Preparations, and P. and C.P. = Panel and Contract Practice.

A Concordance of page numbers and dates of Issue will be found on p. 2.

A

Abdominal pain, chronic, 1128; torsion of omentum (Michael J. Smyth), 372; (Douglas Robb), 1347
Aberdeen University, new Rector of, 1204
Abortion, artificial, nervous and mental indications for, 420; criminal, statistics of (M.L.), 1319; habitual (E. V. Crowe), 79; in Russia, 44; (A.), 1412; treatment of (J. P. Hedley) (M.T.T.), 592, 654
Abraham, J. J., Du-Plat-Taylor, F. M., and Colleridge, John, Cottage Hospitals (R.), 85
Abram, Sir G. S., memorial, 1049
Absinthe, manufacture and sale of (P.I.), 1217
Accident, motor-cycle, 118; outfit for motorists, 944
Accidents, bathing, in the Serpentine (P.I.), 54; fatal street, in London (P.I.), 53; in demolition work (P.I.), 319; street, to children in London (P.I.), 167; to policemen in London (P.I.), 218; to shop assistants (P.I.), 275; traffic, prevention of, 153
Achard, Ch., Œdema of Bright's Disease (R.), 352
Achlorhydria and anæmia in advancing years (Daniel T. Davies and T. G. Illtyd James), 899
Achylia gastrica and pernicious anæmia (A.), 809; (A. F. Hurst) (C.), 873
Acids and bases, metabolism of, 1166
Adams, A., cog-wheel breathing (C.), 713
Adamson, H. W., tuberculosis of skin, 401
Addison, V. H., laxatives and colitis (C.), 993
Addison's disease (Theodore Thompson), 785
Adenitis of iliac glands (R. J. McNeill Love), 135
Adenoid child (Guido Guida), 21
Adenomyxomatous polypoid tumour of stomach (G. Norman Clark), 740
Adhesions, cauterisation of (A. J. Scott Pinchin and H. V. Morlock), 1070; in artificial pneumothorax (G. Maurer), 72
Adie, W. J., permanent hemianopia in migraine and subarachnoid hæmorrhage, 237
Administrative difficulties and finance, 208
Adolescent: His Conflicts and Escapes (Sidney I. Schwab and Borden S. Veeder) (R.), 24
Adrenal atrophy (A.), 146
Adult orthopædic patients, 378; worker, health of (A.), 360
Advertisements of drugs in medical papers (P.I.), 1217
Advertising, medical, by groups, 600
After Consulting Hours (Christopher Howard) (R.), 748
Age-limit, 225, 280, 332
Agents provocateurs, federal, 312
Agranulocytosis (L.A.), 1405
Agricultural produce, purity of (P.I.), 1433
Air ambulance services (A.), 861
Airship disaster (A.), 808
Airships, quarantine for (A.), 304
Air-sickness and sea-sickness, 1074
Aitken, Robert, Ultra-violet Radiations and their Uses (R.), 404
Albuminuria, functional, in children (A.), 113; of pregnancy and its late results, 800
Alcohol and law, 1310
Alexandra Day distribution, 880
Alimentary Anaphylaxis (Guy Laroche, Charles Richet, and François Saint-Girons) (R.), 747
Alkalis in chronic nephritis (A. A. Osman), 945
Allerton, G. T., desiccated hog's stomach in pernicious anæmia, 795
Allier, Raoul, Mind of the Savage (R.), 583
Almata (Keen, Robinson and Co.) (N.P.), 1274
Almoners, course for, 1160
Alpine treatment, assistance to (A.), 860
Alton, twenty-one years at (L.A.), 912
Altounyan, E. H. R., catheter-extraction of ureteral stone per urethram, 399
Alvarez, Walter C., Nervous Indigestion (R.), 1404
Alzheimer's disease, 138
Amberg, Samuel, and Helmholz, Henry F., Diseases of Genito-Urinary System (R.), 1242
Ambulance, student's, 156
Ambulances, home service (A.), 33; air (A.), 861
Amentia (A.), 914
America, medical service problems in, 1325
American Authors, Surgical Diagnosis (R.), 642; "penny-in-the-pound" scheme, 1076; psychopathic hospital (A.), 138; Public Health Association, annual meeting, 421; reception to, 55; students at British universities (Edward Podolsky) (C.), 316
Amrein, O., pulmonary tuberculosis in Switzerland (C.), 315
Amulree, Lord, 864
Amylaceous dyspepsia, 1238
Anæmia, secondary (A.), 704; pernicious (A.), 1247; desiccated hog's stomach in (G. T. Allerton), 795
Anæsthesia, spinal, deaths under (A.), 650; eclampsia treated with (R. H. Paramore), 399
Anæsthetics in childbirth (L.A.), 195; for women in childbirth (P.I.), 1158; in midwifery, 258, 698; *see also* Barbiturates and Avertin
Anal fissure, 332
Analgesia and anæsthesia in childbirth, 698; fatal syncope following percain (W. Howard Jones), 549
Analytical Chemistry, Recent Advances in (C. Ainsworth Mitchell) (R.), 1024
Anatomie médico-chirurgicale de l'abdomen: la région thoraco-abdominale (Raymond Gregoire), 3rd ed. (R.), 746
Ancient Order of Foresters, 378
Andrews, G. C., Diseases of Skin (R.), 802
Andrews, Juston, and Hegner, Robert, Problems and Methods of Research in Protozoology (R.), 967
Angina Pectoris (Harlow Brooks) (R.), 643
Anglo-French Drug Company, diary, 1438
Aniline factory workers, cancer among (P.I.), 1323
Animal cell, synthetic activities of (H. S. Raper), 509
Animals and poison-gas experiments (P.I.), 1157; Bill, slaughter of (P.I.), 1373; cancer in (A.), 1247; experiments on living (A.), 1360; (P.I.), 111, 1047, 1102, 1157, 1375, 1429
Annand, W. Fraser, meningo-encephalitis and herpes zoster (C.), 213
Antenatal supervision (A.), 1359
Anthrax (C. G. Brentnall), 1174
Antiscorbutic vitamin in apples, 279
Antitoxin treatment of diphtheritic paralysis (A.), 1137
Antituberculosis scheme, successful (A.), 1032; schemes, 798
"A. O." (A.), 1030
Apffelstaedt, Max, and Herbst, Emil, Malformations of Jaws and Teeth (R.), 299
"Apoplexy," blood bilirubin in (A), 408
Appendicitis, 600; acute (L.A.), 1133; acute and chronic, in schoolboy, 1126; in schoolboy (L. E. Barrington-Ward), 1116; among Chinese, 1273; mortality from (A.), 1250
Appendix, approaching, through a transverse incision (A. J. Cokkinis), 1396
Apples, antiscorbutic vitamin in, 279
Appointments, weekly lists of, 56, 114, 170, 226, 277, 329, 379, 431, 506, 557, 616, 670, 724, 775, 834, 881, 941, 999, 1051, 1107, 1162, 1219, 1272, 1327, 1377, 1434
Appointments with practice, transfer of (C.), 273
Archibald, E. W., thoracic surgery, 602
Arkwright, J. A., appointment, 253
Army recruits, physical condition of (P.I.), 1217; tests for (P.I.), 1270; physique and health of (P.I.), 318
Arnall, Francis, and Rudge, E. A., chemical examination of silicotic lung, 847
Arneth count, studies on, 1093
Arsenic after sheep-dipping, elimination of (Sir Thomas Oliver), 740; in sweets, 614; (M.L.), 1258; sale of (P.I.), 1374
Artérites et les gangrènes par artérites (Georges Spehl and Edgard Tytgat) (R.), 856

768192

Arterio-venous fistulæ, congenital (Dean Lewis), 621, 680
Arthritis, Chronic (A. H. Douthwaite) (R.), 245
Artificial Cream Act prosecution (M.L.), 821
Artificial light treatment for tuberculosis (G. Lissant Cox), 422; sunlight, 1020; sun-ray treatment (P.I.), 275
Artificial pneumothorax, adhesions in (G. Maurer), 72; apparatus for (G. Marshall) (N.I.), 633
Ashford nurses' hostel, 1160
Asphyxia from coal gas (D. A. Coles) (M.T.T.), 1413; neonatal (Leslie Williams) (M.T.T.), 1033, 1089
Association of American Physicians, annual meeting, 83
Asthma, 173; eosinophilia in (A. Hood) (C.), 272; treatment of (W. R. F. Collis), 567
Asylums, private (P.I.), 53
Athletics and the medical curriculum (L.A.), 807; in Education (Jesse Feiring Williams and William Leonard Hughes) (R.), 86
Atmospheric pollution (A.), 145
Aubrey, G., perversion of taste (C.), 714
Auscultation of muscular tremor (Donald Core) (C.), 936

AUSTRALASIA, CORRESPONDENCE FROM—Hydatid registry, 1036—Needles, broken exploratory, 421—Primary Fellowship examination, 421—Spastic paralysis, ramisection in, 1146

Australia, cancer organisation in (A. Burrows), 330, 380; cancer research in (A.), 704
Australian and New Zealand Medical Association, 1214; hospital tax, 775
Austria, disease, deaths, and births in, 716
Automatic machines, poisons from (M.L.), 99
Autonomic Nervous System (Albert Kuntz) (R.), 403
Autopathography (A.), 651
Autopsy (M.L.), 1034; unauthorised (M.L.), 927, 1414
Autumn conferences, 928
Avertin, 796; in childbirth (J. S. M. Connell), 184; in laryngology (J. Blomfield) (C.), 50; in ophthalmology (A.), 1357, 1438; value of (J. Blomfield), 689
Avery, Harold, Charcot's arthropathy of the sacro-iliac joint, 241
Avicenna, medicine of, 226
Axenfeld, Theodor (O.), 429
Azygos vein, accessory lobe of (G. Gregory Kayne), 1231

B

Bach, Francis, Crowe, H. Warren, Young, T. C. McCombie, Charterhouse Rheumatism Clinic (C.), 1151
Bach, Francis, and Worster-Drought, C., neurosyphilis and cardiovascular syphilis, 1113
Bacharach, A. L., added iron in dried milk, 957; hæmatopoietic properties of dried milk (C.), 1100; and Jephcott, H., toxicity of vitamin D (C.), 1044
Bacteria, effects of castor oil soap on, 117; pathogenic intestinal (Mackenzie Douglas), 789
Bacterial Metabolism (Marjory Stephenson) (R.), 1188; variation (L.A.), 248
Bacteriology, system of (L.A.), 27; in Relation to Medicine (R.), 353
Bacteriolytic agents, filter-passing, transmissible (F. W. Twort), 1064
Bacteriophage and treatment of cholera (L.A.), 647; for dysentery, 764; in cholera (A.), 1248; *see also* Bacteriolytic agents
Baird, Dugald, and Cruickshank, Robert, Dick test in pregnancy, 1009

ADDRESSES AND ORIGINAL ARTICLES

THE FIBROSES OF THE HEART.*

BY JOHN COWAN, M.D. CAMB., D.SC., F.R.F.P.S. GLASG.,
PHYSICIAN TO THE ROYAL INFIRMARY, GLASGOW.

"But it is a great thing, let me tell you, to understand the imperfections of our knowledge, and so to analyse its defects as to be made aware what parts of a subject still remain (as it were) in the shade, and need to be brought into clearer view by the light which future observation may bestow upon them."

So wrote Latham of the diseases of the muscle of the heart in 1845. To-day some of his problems have been solved, some are still undecided, and some still remain in the dark of midnight.

Causes of Fibrosis.

It is a long time since Morgagni recorded the first case of fibroid heart, and it was 100 years later before its causes were appreciated. The old nomenclature "chronic interstitial myocarditis" reflected the earlier views of its causation, and it was only in the eighties of last century that Weigert (1880), Charlewood Turner (1881), and Martin (1881) directed attention to its association with disease of the coronary arteries. The influence of syphilis had already been made known by Ricord (1845) and Virchow (1859). These three causes—myocarditis, ischæmic necrosis, and syphilis—are the chief causes of fibrosis. The other causes—tumour, tubercle, hydatid disease, wounds, and trauma—are of rare occurrence.

In fibrosis of the heart the new formed connective tissue is never uniformly distributed throughout the heart, but is scattered in little islets or bands throughout the muscle. Sometimes only a single patch is present, but most frequently the foci are multiple, and they may be numerous. Their shape varies. They may be rounded, oval, or star-shaped, or a long ribbon of varying thickness. The margins of the patches are always ill-defined and merge gradually into more or less normal muscle. The patches are of all sizes, sometimes mere pinpoints, sometimes blocks even an inch in diameter.

Fibroid patches are most common in the left ventricle though they may be found anywhere. The musculi papillares are most frequently affected, the papillæ becoming shrunken and deformed. The lower third of the left ventricle, the adjacent parts of the septum, and the posterior wall of the left ventricle about the junction of its upper and middle thirds are the next most common sites. On the right side the musculi papillares and the lower part of the ventricle are most frequently involved. The patches may, or may not, extend to the endocardium and pericardium. As a rule they are situated deeply, and do not reach the surface, but if the lesion is gross the overlying endocardium is always thickened, and less frequently the visceral pericardium. In lesser lesions one or other may be involved. If a large area of the wall is affected it is usually thinned, and may measure only a fourth of the normal thickness. But the whole of the muscle cells never completely disappear, a few cells along the endocardial and the pericardial surfaces persisting, being kept alive by the endocardial blood or the superficial circulation.

* The St. Cyres Lecture delivered at the National Hospital for Diseases of the Heart on June 4th, 1930.

ACUTE MYOCARDITIS.

The acute lesions found in the myocardium are varied. In acute infective endocarditis, and pyæmic conditions generally, infective embolism may occur, but the lesions are generally minute because patients with infective myocardial lesions die early. The foci may be due to a direct spread from an infected valve or patch of mural endocarditis, or to dissemination of infected blood through the coronary arteries.

Non-suppurative foci are of common occurrence, especially in cases of rheumatic endocarditis. The nodules are small and invisible to the naked eye. They are most common in the ventricles, especially the left, and are often situated in the vicinity of, or around, an arteriole. The essential lesion is a round-celled infiltration of the tissues. These cells may be few in number, and the adjacent muscle apparently normal; but if they are numerous they infiltrate between the muscle cells which in such case are degenerate. Occasionally they surround a tiny area of necrotic muscle. In most cases the foci are discrete and perhaps widely separated from each other, but the infiltration may be diffuse and larger areas involved. Muir suggests that in some cases the lesion is a focal necrosis of muscle cells, followed by a connective tissue reaction, while in others inflammatory foci around the blood-vessels destroy the adjacent muscle cells. In any case the ultimate results are the same.

In some instances the vessels are similarly affected, an arteritis or phlebitis occurring, often accompanied by thrombosis. The lymphatic channels, too, may be blocked by masses of cells. In later stages islets of connective tissue can be seen surrounding the arteries, and spreading for a variable distance between the adjacent muscle cells.

These myocardial lesions are not confined to cases of rheumatic disease, or indeed to cases of endocarditis. They have been found in many acute infections—pneumonia, pleurisy, diphtheria, sepsis, small-pox, enteric fever, scarlatina, blackwater fever—but they are much more common in the former diseases.

THE ISCHÆMIC FIBROSES.

A large group of cases of fibrosis are caused by interference with the blood-supply through the coronary arteries, which, as is well known, are frequently affected by pathological processes, and almost always show some change after middle life. The orifices may be affected in disease of the aorta, and plaques of atheroma, endarteritis obliterans, and diffuse thickenings are common in the larger and the smaller trunks. In many instances the lumen of the affected vessels is narrowed or blocked, and the corresponding muscle cells are more or less starved. But this is not invariable.

The coronary circulation is peculiar to itself. The two main arteries anastomose with each other at their extremities, and a similar anastomosis obtains between their main descending branches. The terminal vessels also communicate freely with each other, and the capillary network around the muscle cells is large and ample. But although this is so interference with the blood-supply through one vessel is seldom sufficiently compensated by anastomotic developments, and some damage to the muscle as a rule results. I have, however, seen at least five cases in which blocking of one of the main arteries was well compensated by enlargement of the other, and only

a few small patches of fibrosis were found on microscopic examination. Campbell has shown in radiograms of injected hearts the great amount of anastomotic development which may occur in these cases and thus obviate, in large measure, the results of occlusion of an artery. He points out, too, that the distribution of the coronary arteries is very variable, and that the blood-supply of any part may be derived from different arteries in different cases, so that the results of occlusion of a given artery are not constant. The neuromuscular tissues in particular are so lavishly supplied with alternative anastomotic possibilities as to explain the infrequency of blocks in ischæmic disease. But an adequate anastomosis is exceptional; fibrosis, of greater or lesser degree, is the common result of occlusion.

Even in the limbs the possibilities of anastomotic developments are considerable. One of our patients who was suffering from subacute bacterial endocarditis had a rigor on the evening of Nov. 6th, and complained of pain in the chest and the left forearm. Next morning the left arm was rather cold and slightly blue, the colour taking eight seconds to return after pressure upon it as against three seconds in the other hand. The radial pulse was imperceptible and the left subclavian artery was tender and blocked, just beneath the outer end of the clavicle. Two days later the hand was quite warm and the return of blood after pressure more rapid. The artery remained completely closed, but there were no signs of gangrene before his death on Nov. 23rd.

The possibility of effective anastomotic developments depends largely upon the rate of closure of the vessel. If the closure is sudden necrosis results, the area involved varying in size according to the artery concerned. If the closure is gradual some anastomotic developments can take place. In the first case infarct results. In the second some muscle cells undergo ischæmic atrophy while the "less noble" connective tissue survives. In the first case the scar is isolated and massive; in the latter small, paraarterial in site, and perhaps multiple. In infarct, too, hæmorrhage may take place into the softened tissues, and rupture ensue; or, if the wall survives but is weakened, aneurysmal dilatation may occur.

SYPHILITIC LESIONS.

The typical syphilitic lesion is the gumma, but it is rare. Gummata vary in size from microscopic lesions to tumours as large as a pigeon's egg. They may be single or multiple, and may occur anywhere. A diffuse fibrosis, subacute interstitial fibrosis, has been found in the secondary stages of syphilis in the adult, and more frequently in infants and young children in congenital syphilitic disease.

But the most important and the most frequent sequel of syphilis is due to syphilitic disease of the coronary arteries and ischæmic fibrosis. The arteries may be narrowed or occluded at their orifice by a syphilitic plaque in the aorta, or in their course by a specific endarteritis obliterans. Infarct or paraarterial fibrosis results. The ultimate muscular lesions are not specific, though they own a specific cause.

Recognition of Myocarditis.

The symptoms in myocardial disease follow fairly closely their pathological origin. They vary, of course, in different cases, for in some instances the cardiac lesions are merely part of a general arterial disease which has hit first or most severely another branch of the arterial tree; while in others they are the essential feature. They vary in their mode of onset. If a vessel is suddenly occluded the onset of symptoms is abrupt, while it is insidious if the lumen is slowly narrowed. In some cases a progressive narrowing is succeeded by a sudden thrombotic closure, and an acute exacerbation follows on a chronic train of symptoms. Thrombosis, too, may occur within the cardiac cavities, and embolism, anywhere, may suddenly alter the clinical picture. Often pericarditis ensues, and, though usually a subsidiary affair, may even dominate the scene. Sometimes, too, the primitive tissues of the heart are hit, the intrinsic mechanism of the heart is deranged, and a change of rhythm (e.g., heart-block) imparts its special feature to the clinical syndrome.

The dramatic attacks of ischæmic disease of the myocardium contrast strongly with the complaints of acute myocarditis. In the former, pain is often a striking symptom, the onset is sudden, and the most serious symptoms immediately precede death. In the latter, pain is exceptional unless pericarditis supervenes; the onset is generally insidious; and serious symptoms may occur early in the illness. In acute myocarditis, too, its symptoms are masked in great measure by the symptoms of the primary illness, and can only be differentiated with difficulty.

Acute myocarditis is most common in cases of acute endocarditis, whether of rheumatic or other origin, and in diphtheria, though it may obtain in almost any infection. In the infections as a whole the granular, fatty, and hyaline degenerations which are constantly present in the heart, are largely responsible for the cardiac asthenia, and although one might infer a priori, from our pathological knowledge, that myocarditis is present in every case of acute endocarditis actual evidence of its occurrence during life is only afforded by the appearance of some disturbance of the cardiac rhythm, sign of interference with the intrinsic mechanism of the heart. We know, too, that arrhythmia is often due to functional or nervous derangements, and that the heart-blocks alone are definite evidence of myocarditis. In a few cases the occurrence of a nodal rhythm, or progressive cardiac failure without obvious cause, afford presumptive evidence of its presence.

The first cases of heart-block in acute disease were recorded by Jellinek and Cooper (gonococcic endocarditis), James (malignant endocarditis), and Gerhardt (enteric fever with arthritis) in 1908; and two years later Magnus Alsleben reported its occurrence in diphtheria, a disease in which it has been frequently observed.

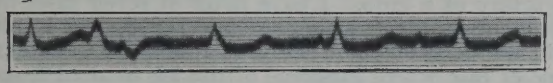
The occurrence of heart-block in myocarditis is occasionally accompanied by the Adams-Stokes syndrome; in a case of this kind in Sinai during the war, in a patient who was suffering from diphtheria, the attacks were numerous. But this is unusual; cardiac symptoms alone are the rule.

A man, aged 40, was taken ill seven weeks before admission into hospital with a typical attack of rheumatic fever. He remained in bed for a fortnight and at once resumed work, but after a few days had a recurrence of his arthritis and was again confined to bed for a fortnight. He again resumed his work, but three days later, while dressing, he was seized with acute pain beneath the sternum accompanied by breathlessness and palpitation, and collapsed. When admitted into hospital a fortnight later he was very breathless and pale with a small irregular pulse which numbered about 66 per minute. The heart was dilated, the liver large and tender, and the bases of the lungs congested. He died next morning. An electrocardiogram showed full heart-block, the auricles running about 78 and the ventricles at 59, their regular rhythm being interrupted at intervals by right ventricular extrasystoles (Fig. 1). The post-mortem examination showed the explanation of the block. The mitral cusp of the aortic valve was involved in an acute inflammation which had spread deeply, affecting the adjacent parts of the anterior mitral cusp, producing a small aneurysmal pouch, as well as the adjacent parts of the interventricular septum. Spreading through the septum it had infected the septal cusp of the tricuspid valve. As the lesion involved the septum immediately behind the undefended space the bundle of Kent must have been directly affected.

A partial block is more common.

A man, aged 21, was admitted into hospital suffering from rheumatic fever of two days' duration. His pulse was quite regular and of fair value, but during the night it became irregular and less frequent, 84 against 110 on admission. Electrocardiograms showed a partial heart-block, every third auricular beat failing to evoke a ventricular contraction. Next day the pulse numbered 70 and was still irregular but the missed beats were less frequent. On the day after the pulse was regular and numbered 80, each auricular beat being followed by a ventricular contraction, and the P–R interval measured 0·22 sec. Two days later the pulse was occasionally irregular, the P–R interval measuring about

FIG. 1.



Full heart-block with one extrasystole.

0·24 sec., and some ventricular contractions failing. The pulse subsequently was always regular, and the P–R interval soon returned to normal limits.

Still more frequently a latent block is shown on examination, the pulse remaining quite regular.

One of our patients who died at the age of 26 from acute endocarditis showed during life a regular pulse which invariably exhibited a prolonged a-c interval of about 0·25 sec. Post-mortem examination showed an early interstitial myocarditis, the muscle cells in some of the patches being degenerate. The a-v node was congested but otherwise normal. The bundle was involved in three places in inflammatory foci similar to those found elsewhere.

Block of these varying degrees is not uncommon in acute rheumatism. In our series of 428 cases of acute rheumatism block was *recorded* in 13.

The diagnosis of bundle branch block is only possible by electrocardiography, for, unlike heart-block, it gives no sign of its occurrence by alterations in the rate and regularity of the pulse. Its incidence is, in consequence, not yet fully recognised. It is most commonly found in patients who are suffering from chronic myocarditis, the result of ischæmic fibrosis. The left branch with its ribbon-like form and its ample blood-supply, derived from both coronary arteries, is but seldom affected, while the right branch, a slender strand, supplied by the anterior septal branches of the left coronary artery, and occasionally by the ramus cristæ supraventricularis, a branch of the right coronary artery, is more often found to be defective. Mural endocarditis is rarely present on the right side of the heart, and bundle branch block is rarely due to myocarditis. In the only case in which myocarditis seemed the probable cause, the patient was a man, aged 51, who had had an attack of acute rheumatism a few months before accompanied by aortic valvular disease. The block persisted until his death six years afterwards.

In three cases a temporary block has been recorded, which suggests that the cause may have been a myocarditis. In Lewis's case the block was present during a febrile attack; in Ritchie's case when the patient was jaundiced; and in Hewlett's case when the patient was suffering from urinary sepsis. We must remember that blocks may be produced by such drugs as digitalis, aconitine, and muscarine, and so presumably by toxic causes, without definite structural disease; but their influence is generally transient. In the absence of such intoxications, and the presence of an acute endocarditis, the existence of acute myocarditis may be fairly assumed.

NODAL RHYTHM.

Nodal rhythm may be produced in experiment in two ways—by throwing the sino-auricular node out of action, thus permitting the auriculoventricular node to become dominant and to regulate the action of the heart; and by enhancing the activity of the auriculoventricular node, so that superseding the sino-auricular node it sets the pace of the heart. In the first case the rate of the heart is slowed; in the second the rate is increased.

Clinically three groups of nodal rhythm may be distinguished. In one paroxysms of nodal tachycardia occur from time to time; in another the cardiac rate is infrequent or but slightly increased; in the third the pulse-rate is persistently rapid. The first group are manifestly due to functional causes; the second occur under diverse conditions, sometimes in patients who are not labouring from any cardiac disorder; the third are sometimes associated with myocarditis. In one case a continuous nodal rhythm was present for a month before death, the pulse-rate ranging between 110 and 140, with a regular rhythm.

The patient was a woman aged 27 who had suffered from acute rheumatism in 1900 and 1910. The second attack was severe and prolonged, but she made a satisfactory recovery. A year later she gave birth to a healthy baby, and four months later a third attack of rheumatism ensued. She returned at once to hospital, seriously ill with arthritis and pneumonia. Her progress was unsatisfactory, the fever persisting and congestive failure appearing. She died two months later from cardiac failure. Post-mortem examination showed an adherent pericardium and chronic endocarditis of the aortic and mitral valves, an acute endocarditis being present on both these valves and also on the tricuspid valve. An extensive fibrosis was present in the muscle, spreading from the mitral valve into the auriculo-ventricular node, in which there were many fibroblasts and round cells. The lesions found were evidently of different ages, the older ones perhaps dating from the illness of 1910, though no direct evidence of myocardial mischief was elicited at that time. The more recent lesions, too, were evidently of some standing, as the fibroblasts in the cellular infiltrations were numerous, a fact which may be correlated with the appearance of the nodal rhythm a month before death. The earlier tracings were of sinus character.

In the records of six cases of this kind, in which microscopic examination of the muscle showed inflammatory lesions in the auriculoventricular node, three of these patients were suffering from acute rheumatism and three from infective endocarditis.

Progressive cardiac failure, *without obvious cause*, is always suggestive of myocardial lesions, which in some cases may be assumed to be inflammatory in nature.

A man, aged 22, died in our wards in May, 1920. He had had rheumatic fever in 1911 and 1914, and had made a good recovery, though left with a mitral leak. He worked regularly throughout the war, but in the spring of 1919 he undertook rather arduous work and cardiac symptoms soon supervened. He re-entered the ward in May, 1919. At this time he had some bronchitis, and his auricles were fibrillating, but steadily improved on the subsidence of the catarrh and the administration of adequate doses of digitalis. In December he was walking four miles daily for recreation. In January, 1920, he caught cold and all his symptoms returned. As the pulmonary lesions improved his discomforts lessened, and he was able to walk about the ward. But the improvement was evanescent, and in April it was clear that his heart was failing. He died in the middle of May.

There was no obvious immediate cause for the fatal termination. His symptoms in the spring of 1919 had been associated with excessive physical exertion, and in the beginning of 1920 with bronchitis. But none of these were active in March, April, May, though the cardiac failure was progressive, and his heart steadily dilating. His age and the state of his arteries negatived ischæmic fibrosis, and the probable cause of the progressive failure seemed to be myocarditis, the sequel of a subacute endocarditis. Post-

mortem examination showed the correctness of the assumption, a gross chronic lesion of the mitral valve being found with slight acute lesions of the mitral, aortic, and tricuspid valves, and widespread acute and subacute myocardial inflammation.

Clinical Features of Ischæmic Fibrosis.

The symptoms of ischæmic fibrosis differ from those of myocarditis. The dominating symptom is cardiac pain, though pain is not invariably present; the onset of the symptoms is usually sudden; and death *may* occur suddenly at any time without warning.

ANGINA PECTORIS.

The current theory of angina pectoris is a revival of an old idea which was first formulated by Allan Burns in 1908, and has been elaborated from the experimental side by J. A. MacWilliam (with W. J. Webster), in 1923, and from the clinical side by C. S. Keefer and W. H. Resnikinin 1928. According to this theory angina is the result of anoxæmia of the heart—a physiological conception, not an anatomical finding.

Allan Burns's statement may be quoted :—

"In health when we excite the muscular system to more energetic action than usual, we increase the circulation in every part, so that to support this increased action the heart and every other part has its power augmented. If, however, we call into vigorous action a limb round which we have, with a moderate amount of tightness, applied a ligature, we find that then the member can only support its action for a very short time, for now its supply of energy and its expenditure do not balance each other; consequently, it soon from a deficiency of nervous influence and arterial blood fails and sinks into a state of quiescence. A heart, the coronary arteries of which are cartilaginous or ossified, is in nearly a similar condition. It can, like the limb begirt with a moderately tight ligature, discharge its functions so long as its action is moderate and equal. Increase, however, the action of the whole body, and along with the rest that of the heart, and you will soon see exemplified the truth of what has been said; with this difference that as there is no interruption to the action of the cardiac nerves the heart will be able to hold out a little longer than the limb."

MacWilliam approached the question from the experimental side. He applied a tourniquet to the arm and noted the results: (*a*) so long as the forearm muscles remained inactive; and (*b*) when these muscles were thrown into action. As he found that the symptoms might, in part, be due to turgescence of the limb if the constriction was applied suddenly, he made the limb ischæmic by means of an elastic bandage, applied first to the fingers and the hand, and only removed after the tourniquet had been applied.

In a limb thus treated and kept *immobile* no notable result followed for the next 20 minutes, save for some coldness in the parts, an inclination to shift the position of the arm, and a certain amount of discomfort at the site of the constriction. Muscular activity of the forearm muscles, however, rapidly produced notable discomforts. Fatigue, as measured by the number of contractions executed within a given period, and their force, was readily produced, the fatigue point being reached in half or one-third of the time required in the normal limb. The forearm, too, rapidly became painful, and as the fatigue point was approached, so acutely painful, that the desire for relief became urgent. Cessation of the exercise, too, did not relieve the pain, which only ceased after relaxation of the constriction and the advent of fresh blood to the ischæmic muscles. Though relief of pain was thus readily afforded, fatigue was still apparent, and only passed off after some interval of time.

"It need hardly be pointed out," said MacWilliam, "that the foregoing observations have a close bearing upon the problems associated with the production of pain in angina pectoris, showing as they do how readily acute pain can be excited in skeletal muscles working with lack of blood-supply, the pain developing while the contractile power, though to some extent weakened, is still sufficient to execute movements of considerable force and energy—that is, long before complete fatigue."

Comparable experiments occur from time to time in clinical work. We are all acquainted with the pain of intermittent claudication, the sudden gripping of the calf muscles and the weakness of the legs, which ensues in patients with narrowing of the arteries of the legs if the demand for more blood to meet the demand for physical exertion cannot be satisfied at once. We know, too well, the pain of senile gangrene; and pain is a constant feature in embolic blocking of an artery of a limb. I have notes of seven cases of this kind in which gangrene supervened, and in all pain was a serious and early symptom. In another type of case where gangrene of the leg resulted from thrombosis of a popliteal artery the pain was severe and clamant. The patient was walking home from work when he was suddenly seized with acute pain in the leg, so acute that he was able only with difficulty to reach his home a hundred yards away. When admitted into hospital a few hours later the pain was still severe.

It may seem difficult to correlate such occurrences with angina pectoris. Angina occurs in such diverse types of case. It is found in patients with and without heart disease, associated with a high and a low blood pressure, after operations and pregnancy, in patients with high and low blood counts. What common factor can obtain among these patients?

Keefer and Resnik analysed a series of 399 cases of angina, including 13 cases of their own, in whom post-mortem examinations had been made. In all but 19 cases the coronary arteries were diseased, and in the exceptions the aortic valves were incompetent. *Viewed from the physiological standpoint* an anoxæmia of the cardiac muscle can readily be assumed to occur under certain circumstances. Disease of a coronary artery will necessarily limit the flow of blood to the parts concerned, and the blood-supply, while sufficient for the muscle if working quietly, may be insufficient if the extra strain of physical exertion or some temporary elevation of the blood pressure is added. In aortic incompetence the diastolic pressure is low, and as the cardiac muscle is supplied with blood during diastole some ischæmia must necessarily obtain, even when the patient is at rest. In many cases, too, the aorta as well is diseased, and the orifices of the coronary arteries are narrowed and the ischæmia consequently exaggerated.

Angina is rare in mitral disease, for congestive failure rapidly ensues on exertion, and the dyspnœa checks exertion before the painful stage of anoxæmia occurs. It is rare in the severe anæmias, as all the tissues of the body are concerned and the general flabbiness prevents the possibility of undue strain upon the heart. But in disease of the coronary arteries *only a part of the heart* may be involved, the greater part of the muscle being unaffected. The heart can thus respond effectively to a demand for increased activity, but the part whose blood-supply is limited now becomes relatively ischæmic and so gives rise to painful sensations. The liability to angina can coexist with the possession of considerable power by the heart as a whole. Intermittent claudication and embolic blocking of the peripheral arteries are exactly comparable to angina and ischæmic necrosis of the heart. If the circulation is impaired symptoms will only ensue if exertion renders the parts relatively anæmic, while if the block is complete the symptoms will continue indefinitely.

Many patients who suffer from angina tell us that while they are capable of undertaking considerable exertion under favourable conditions attacks ensue if they are exposed to cold winds, if exercise is undertaken immediately after food, or if they are subjected to nervous strain. John Hunter's case at once returns to our memory. Prof. MacWilliam says :—

"So far as my observations go there is not necessarily such rise of blood pressure on exposure to cold as would throw a decidedly greater strain upon the heart. It seems to me that some transient attacks of pain, with no obvious and sufficient exciting cause, probably depend on a central nervous factor, an increased susceptibility to pain from irritant impulses arising in the heart. Exposure to cold, for instance, often tends to excite neuralgic pains, anywhere, in a susceptible person."

Such an explanation seems more than plausible. Many of these patients are highly strung and very intolerant of their discomforts. Several patients, too, have informed us that their attacks cease *instantaneously* as soon as they have swallowed a tablet of trinitrin, and before any effects of the drug could have been manifested. Vasomotor alterations in the distribution of the blood may also play a part. "If you eat till you're cold you will live till you're old," the vasomotor reply to the need for an increased blood-supply to the digestive organs after a meal, may perhaps lessen the supply of blood to the systemic arteries elsewhere.

20.ii.30. 1.iii.30.
Note the changes in QRST after the attack of 26.ii.30.

VARIETIES OF ANGINAL ATTACK.

It has been my lot to witness a considerable number of attacks of angina. I can see still the anxious expression of a colleague during a seizure, his sweat-bedewed features, his absolute immobility, even his breathing being checked, and his inaudible declinature of a proffered hypodermic injection.

In a second case death occurred. The patient had been ill for some months with attacks of pain which were becoming more frequent and more severe. He drove into town with his doctor, and chatted happily during the drive. On arrival he hurried across the pavement and up the steps of the house, and pain at once supervened. When seen a few minutes later he was sitting restlessly upon a chair, complaining of acute substernal pain which shot down into both arms. He was flushed, excited, and talkative, and tried to make himself more comfortable by changes in position and attempts at retching. After the administration of some amyl nitrite and brandy, the pain abated in severity, but he was conscious that the attack had not ended. In a few minutes an exacerbation occurred, followed by a remission, and again by an exacerbation of the pain. He was coughing from time to time, and expectorating some mucous fluid which was slightly tinged with pink. The attack had now lasted for half an hour, and the pulse failed perceptibly for some moments, but steadied before any stimulant could be applied. His face, at first flushed, became ashen and bluish. The pain again recurred in great severity, the pulse failed, and he died 45 minutes after entering the house.

The pain varied in intensity but never completely remitted. It did not immobilise him and he moved restlessly and talked almost continuously. The pulse at first was a little frequent, full, and quick. During the acme of the pain its rate increased but probably never exceeded 120. It was always regular, the failure in volume and strength being the striking feature.

A third case may be quoted. The patient had had attacks of angina for a year before his admission into hospital, and on the day prior to his admission a severe attack which persisted for 36 hours. Subsequently, his attacks were minimal and of short duration. But on Feb. 26th a severe attack ensued about 9·20 A.M., and continued until the afternoon. When seen a few minutes after the onset he looked very collapsed, and complained of severe pain in the epigastrium extending up into the chest and down the left arm as far as the wrist. His pulse, which had been running in the 80's, was now over 100, and had lost notably in volume and strength. The cardiac sounds were distant and indistinct. In the afternoon the pain passed away and his pulse regained some of its former quality. For the next six weeks his symptoms remained more or less in abeyance until one evening, when some friends were visiting him, an attack supervened. He died almost instantaneously. (Fig. 2.)

In the first of these three cases the pain was intermittent and of short duration. In the second case it persisted and cardiac failure rapidly followed. In the third case, during the attack which was observed, the occurrence of pain was accompanied *at once* by grave cardiac failure, which continued for some weeks. In the first case the anoxæmia was relative and temporary; in the second relative at first, but continued; in the third absolute and continued. In this last case examination revealed a large infarct of the apical part of the heart, due to occlusion of the descending branch of the left coronary artery.

In another group the symptoms are those of congestive cardiac failure. The onset may be sudden or insidious.

A labourer, aged 63, while climbing up a gangway on to a ship suddenly became extremely short of breath and was unable to proceed. His fellow workmen pulled him on to the deck and he soon felt better and was able to go home, where he stayed for four days. As he then felt quite well he resumed his work, but he at once became short of breath and had to take to bed two days later. His feet became swollen, his breathlessness increased, and orthopnœa ensued. He was restless and slept badly. A few days later he began to experience pains in the front of his chest and all his discomforts became intensified. Three weeks after the initial seizure he coughed up a considerable amount of blood, and the hæmoptysis continued. When admitted into hospital a few days later he was collapsed, cyanosed, and cold. His pulse was regular, of moderate pressure, and quick. The heart was normal in size and site and the sounds, though distant and indistinct, were pure. Œdema was extensive, the liver was enlarged and tender, and the bases of the lungs were dull to percussion. He remained in much the same condition for five days, and then died suddenly.

On examination an infarction of the lower two thirds of the left ventricle was found, the wall being thinned and bulging. The left coronary artery was blocked about an inch below its origin. A subacute pericarditis explained the appearance of thoracic pain in the *second* week of his illness.

In the following case the onset of the symptoms was insidious.

The patient, a painter aged 51, was a healthy man who had had an attack of "influenza" at Christmas, for which he was confined to bed for three weeks. When he resumed his work he found that he was short of breath upon exertion, and felt his heart beating. Two months later he caught cold and bronchitis developed. His ankles became swollen and

the dyspnœa and palpitation worse. He was forced to take to bed in the beginning of March. When admitted into hospital on April 18th he was very short of breath and had to sit up in bed. The feet were œdematous, the liver enlarged, and dullness was present at the bases. The heart was enlarged in both directions, the cardiac sounds were short and of poor quality with a systolic murmur at the base. The pulse was regular, with a blood pressure of 150–110 mm. Hg. His progress was unsatisfactory. Some improvement occurred from time to time, but was invariably of short duration. Infarcts occurred in the lungs, and in August his blood pressure began to fall, touching 110–80 mm. in September. Pneumonia ensued in October, and he died in a couple of days.

Examination showed widespread atheroma of the coronary arteries, the descending branch of the left vessel being almost occluded two inches below its origin, while the right vessel was greatly narrowed in more than one place. A gross fibrosis of the apical third of the left ventricle was present, apparently a dystrophic fibrosis and not the result of infarct.

In another group the symptoms are those of disturbance of the cardiac rhythm. Of these the most common is heart-block, which is sometimes accompanied by the Adams-Stokes syndrome. One case may be mentioned.

The patient, a man aged 47, was in hospital on account of pains in his chest and shortness of breath which had succeeded a "cold." He had well-marked aortic valvular disease, the result of rheumatic endocarditis many years before, and he had been in hospital on account of cardiac insufficiency on two previous occasions. On the day following his admission, at 3·40 in the afternoon, he had an epileptiform attack which lasted for five minutes. His pulse, which at noon had numbered 112, was now 32, and subsequently fell to 22. It remained infrequent until four o'clock the next afternoon, when it was found to number 84. His subsequent progress was good. Electrocardiograms taken during the period of infrequent pulse showed full heart-block. Next day the rhythm was of sinus origin, with a P–R interval of 0·32 sec. A week later it measured 0·20 sec., and a week later 0·14 sec.

In yet another group the symptoms are those of disease in organs other than the heart, due to similar arterial causes, no special suggestions of cardiac difficulty being present, and the diagnosis being made on the post-mortem table. Cerebral symptoms are most common, and were due in this series to embolism, thrombosis, and rupture of a cerebral aneurysm. Several of our clinical series have had strokes before or after cardiac seizures. One of our patients died from chronic uræmia, the sequel of cirrhotic kidneys.

The last but by no means the smallest group is of little clinical interest, the cases of "sudden death" whose cause is only ascertained after death. It seems to contain almost every case of gumma of the heart (Herringham) as well as many cases of ischæmic necrosis and rupture of the heart.

The Diagnosis.

The recognition of myocardial fibrosis depends partly upon the story of the illness and partly upon the physical signs. If we are correct in our conception of the causes of angina its occurrence, apart from aortic valvular disease, pregnancy, operations, or severe anæmia, indicates interference with the coronary blood-supply, and hence a potential or an actual fibrosis. Infarct, heart-block, and bundle branch block are, too, indications of fibrosis.

The diagnosis of angina is founded on the story of the patient. The occurrence of pain in the chest on exertion, however slight, is the criterion. The early symptoms are often trivial, their significance is missed, and the diagnosis is made too late for effective treatment to be possible. There is no difference of kind save in degree between angina and infarct, though the clinical syndrome differs. At the present time it is unnecessary to refer in detail to the differential diagnosis, which is well shown in the following table, based upon the tables of Keefer and Resnik and of Bedford and Parkinson.

	ANGINA.	ISCHÆMIC NECROSIS.
Anoxæmia	Relative and transient	Absolute and permanent.
Pain	Of short duration	If present prolonged.
	Occurs on exertion and so diurnal	Occurs without obvious cause and often nocturnal.
Epigastric pain	Rare	Not uncommon.
Amyl nitrite	Often relieves	Has no effect.
Rest	Relieves	Has little or no effect.
Attitude	Immobile	Restless.
Cardiac failure	Rare	Often, indeed usually, present.
Dyspnœa	Rare	Often present.
Pulse—		
Rate and rhythm	Often unchanged	Often altered.
Blood pressure	May be high	Usually falls.
Electrocardiogram	Often abnormal	Usually abnormal.

One symptom which is not uncommon in infarct demands more attention. The pain is not infrequently referred to the abdomen and associated with gastric symptoms.

One of our patients played a game of golf in the afternoon, and then set off to drive home, apparently in his usual health. Engine trouble ensued and he was delayed, and, as he was late for dinner, he drank some beer. On his arrival home late at night he complained of sickness and vomited on several occasions. He went to sleep about midnight, but was wakened a couple of hours later by severe pain in the front of the chest which radiated into the left arm. The pain necessitated repeated doses of morphia, but lessened in the course of the day. The nausea persisted and he was much troubled with flatulence. For 36 hours after the onset of his symptoms no evidence of cardiac disorder was apparent. The heart was normal in size and site, the cardiac sounds were within normal limits, the pulse was regular, beating at 84 per minute, with a blood pressure of 138–84 mm. (about his usual figure). Pericardial friction was then detected by Dr. A. S. Henderson, who found a pulse-rate of 108 and a blood pressure of 114–80 mm. The gastric symptoms persisted for the next week.

Another patient, who for some months had had several attacks of dyspnœa on exertion, was suddenly, while brushing boots, seized with acute pain about the right breast which passed back into the scapular region, accompanied by retching and vomiting. The sickness and pain persisted all day, notwithstanding the administration of morphia. He had a restless night, and next day was still sick while the pain was less acute. Next morning, 48 hours after the onset, Dr. J. L. Anderson detected pericardial friction. The heart previously had seemed to be normal. The pain was now absent save on movement, but the nausea and flatulence persisted.

Another patient who had suffered for some years from symptoms of cardiac distress complained one day of pains in the abdomen which did not, however, confine her to bed. On the fourth day she was unable to rise and returned at once to hospital. Her complaints were purely abdominal. She had a coated tongue and much flatulence. Her cardiac condition seemed unchanged. She rapidly improved, but three days later became restless and heady, and required a sedative at night. Next morning she was very well and sat up and joked with her neighbours, but at 11 o'clock was seen to become cyanosed quite suddenly and died in five minutes from rupture of the heart through an infarct of the left ventricle.

Another patient had a laparotomy performed for similar symptoms, and recovered from his treatment for the time. He died six months later with cardiac symptoms. An infarct was found about the apex of the left ventricle and the septum.

It is useful to remember that the blood pressure in adults is rarely beneath 120 mm. in the absence of some cardiac disorder.

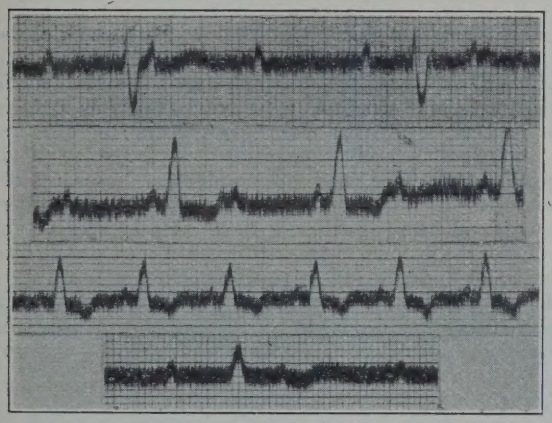
In a certain number of cases definite evidence of myocardial disease is shown by the electrocardiogram, but too much must not be expected from this form of investigation. The electrocardiogram is the record of the changes in potential produced by the orderly mass contraction of the two hearts. If the orderly sequence of events is interrupted by myocardial lesions hitting the bundle branches and interfering with their function abnormal deflexions will occur

in QRS. But lesions elsewhere do not necessarily deform the picture. Deformities will only occur if the mass of tissue thrown out of action is considerable in size and localised. Small focal lesions, whether scanty or numerous, are unlikely to deform the curve, especially if they are more or less uniformly distributed throughout the heart. It must, too, be remembered that a deformed electrocardiogram may return to normal after an infarct, if the process of healing removes the want of balance between the different parts of the heart, or its irritating influence ceases. The records are thus merely the records of damage to the muscle, and in no way an index of the cause of the damage. They may, too, be altered by associated disease of the cardiac valves, or high blood pressure in the systemic or pulmonary circuits.

In cases of angina careful examination of the heart usually reveals some definite abnormality, an increase of the size of the heart, a high or low blood pressure, abnormal cardiac sounds or electrocardiograms. But occasionally the heart seems to be quite normal.

This was the case in a patient aged 63, who had had anginous symptoms for several years. The heart was perhaps a trifle large, but the sounds were pure and of average quality, and an electrocardiogram showed normal

FIG. 3.



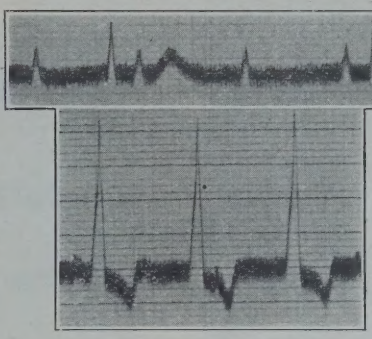
Lead I. The dates of the electrocardiograms, from above downwards, are March 26th, 1926; Sept. 6th, 1927; Feb. 28th, 1929; and Jan. 6th, 1930.

deflexions. His blood pressure was 150–105 mm. A month later he died suddenly after walking home, uphill, against a strong wind. A post-mortem examination of a man, aged 47, who died shortly after admission to hospital, affords an explanation of these cases. He had suffered for a couple of months from anginous attacks. There was a well-marked syphilitic aortitis which had caused a marked stenosis of the orifices of the coronary arteries, the vessels in their course and the myocardium being apparently perfectly healthy. An electrocardiogram would, presumably, have been quite normal.

In the large majority of patients with myocardial lesions, however, some abnormality is apparent on examination. The apex impulse may move outwards. In one of our patients who had an acute endocarditis, with myocarditis, the apex was situated 13·5 cm. from midsternum in May, 14 cm. in September, 15·5 cm. in February, and 16·5 cm. in May, just before his death. The apex impulse may disappear at first only when the patient is lying on his back, reappearing when he lies on his side; but later on whatever his position. The cardiac sounds may alter, losing loudness and becoming shorter, and the first sound may become impure from incompetence of the mitral or tricuspid valve. Or the relative intensity of the aortic or pulmonary sounds may alter from a failure of one or other ventricle. The electrocardiogram may show progressive alterations.

In the majority of patients who have heart-block the block persists for the rest of their life, but this is not always so. We have already mentioned a case

FIG. 4.



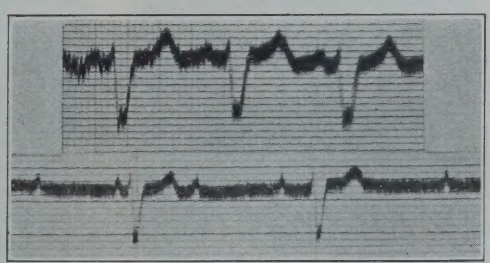
Electrocardiograms taken on July 4th, 1919 (above), and Oct. 10th, 1919 (below).

in which full heart-block only lasted for 24 hours. In another patient heart-block was present on August 3rd and had disappeared on the 10th. In the following case a full heart-block passed away to recur about two years later.

The patient is now aged 66, and works all morning in his office. He had always been a healthy man, save for an attack of dysentery on the Peninsula in 1915. In 1919 he had an attack of shortness of breath at a picnic, and again in 1923 when rolling the lawn, having to lie down on both occasions for some minutes before he recovered. In 1924 he had an attack of pain in his chest when riding. During the winter of 1924–25 he complained of shortness of breath upon exertion, but continued at his work. On May 7th, 1925, he went to a cinema, and when returning home nearly died from cardiac failure while climbing up the stair of a tram-car. When seen shortly afterwards he was very collapsed, with a regular feeble pulse of 44. He made a slow recovery. In the summer of 1928 he had an attack of dysentery which kept him in bed for a few days. In September, 1929, he had an attack of influenza, and two months later fainted when in his office. Otherwise he has been in comfort, working in his office and taking little exercise.

The changes of rhythm have been striking. A polygraph tracing on May 11th, 1925, showed full heart-block, and an electrocardiogram on March 26th, 1926, showed a similar rhythm. On Sept. 6th, 1927, a 2–1 block was present. On Feb. 28th, 1929, the rhythm was normal save for some

FIG. 5.



Bundle branch block on Nov. 24th, 1928 (above) and full heart-block as well on Dec. 14th, 1928 (below).

auricular extrasystoles, but on Jan. 6th, 1930, full heart-block was again present, having apparently recurred at the time of the syncope in November, 1929, as the pulse which in September had been running at 80 was then found to number 40 (Fig. 3). The variations in his blood pressure are very interesting. In 1926, when the block was full, it measured 215–70 mm.; in 1927, with the 2–1 block, 175–70 mm.; in 1929, with a normal rhythm, 160–110 mm.; and in 1930, after the return of the full block, 240–94.

Bundle branch block, too, may occur under similar conditions. An old man who was in the wards suffering from full heart-block with Adams-Stokes symptoms showed a full heart-block in July. During the autumn he was evidently slowly failing, and in October a routine examination showed right bundle branch block as well (Fig. 4). (You must use the wet fly if you wish to catch bundle branch block!) The opposite sequence was detected in an old lady who was suffering from recurrent syncopal attacks, due to coronary disease. The electrocardiogram of Nov. 24th showed left bundle branch block, while that of Dec. 14th showed as well full heart-block (Fig. 5).

But the most common changes are in the ventricular complex.

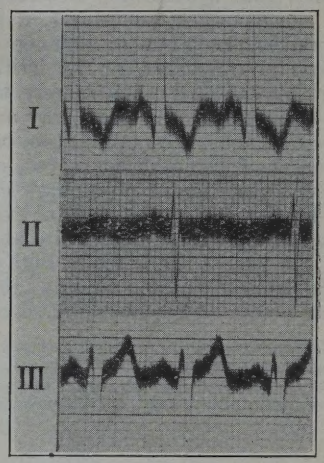
Inversion of T in lead III.

FIG. 8.



Inversion of T in lead I.

ELECTROCARDIOGRAM IN MYOCARDIAL INFARCT.

The changes in the electrocardiogram have been studied most fully in cases of myocardial infarct, but serial records, with post-mortem examinations, are still too few for accurate deductions to be possible. The following account is based upon the recent paper by Rae Gilchrist and Ritchie.

The early changes in infarct are usually shown as a deviation of the R–T segment from the iso-electric level. The deviation may be upwards or downwards, the direction in leads I. and III. being opposed. In the course of a few days or weeks the curve alters, negative T waves, which may be of exaggerated size, appearing, running out of QRS without any iso-electric period. The subsequent changes are in the direction of normal, which may be attained, or a negative T may persist indefinitely. But, as Gilchrist and Ritchie point out, R–T deviation may occur in various toxic conditions, such as digitalis and antiarin poisoning, in perfusion with variations in pH, in uræmia, and asphyxia. Moreover, T may be affected by emotion, exercise, exposure to heat or cold, digitalis poisoning, and preponderance of the left ventricle. In the absence of these factors, however, changes of the kind described are indicative of myocardial lesions. An abrupt onset points to infarct, an insidious onset to fibrosis.

These changes, too, are not invariably present in cases of myocardial infarct; R–T deviation was not present in 41 of 93 cases of their series, and T was not inverted in eight of 25 cases of coronary sclerosis confirmed by post-mortem examination.

Personal experience coincides with Gilchrist and Ritchie's conclusions, for in 12 cases of gross myocardial damage, examined post mortem, the electrocardiogram failed in 4 to reveal characteristic changes. Changes are, however, often striking. Fig. 6 shows R–T deviation in leads I. and III. two

months after an attack of acute dyspnœa, during which the pulse for a time failed completely. Fig. 7 shows notable inversion of T five weeks after an attack of acute thoracic pain accompanied by great cardiac weakness, which had ensued on exertion. Fig. 8 shows well-marked inversion of T, in the opposite direction, three months after an attack of acute thoracic pain and breathlessness which had awakened the patient from his sleep. Fig. 9 shows other changes, associated with broadening of QRS, obtained five months after the onset of "tightness" of the chest upon exertion, followed a couple of months later by a full attack of angina. Fig. 10 was obtained from a man who three weeks previously, on a hot summer day, had suddenly become very giddy. The giddiness persisted. Fig. 11 was obtained from a woman who had had an attack of shingles and was found to have a mitral systolic murmur.

Fig. 12 shows a not uncommon alteration of lead III.

The patient first came under observation in 1925, when he complained of shortness of breath upon exertion which had succeeded a catarrh contracted some four months before. It seemed possible that he was suffering from whooping-cough, with which his children were at that time affected. The heart seemed normal on examination. In the summer he improved, and resumed his golf. In January, 1927, he again caught cold, and his breathlessness returned. He was confined to bed for a week, and on his return to business found that he was very short of breath upon even trivial exertion. The electrocardiogram now showed definite R–T deviation, most distinct in lead III. Otherwise the heart seemed quite normal. He refused to take care, and went a golfing holiday which confined him to bed for ten days. Return to business again produced an exacerbation of his discomforts, and he had to return to his bed. One evening he complained of some discomfort or pain in the epigastrium, which persisted next morning. But he sat up in bed dictating letters, and suddenly fell back dead.

We have watched somewhat similar electro-

FIG. 12.

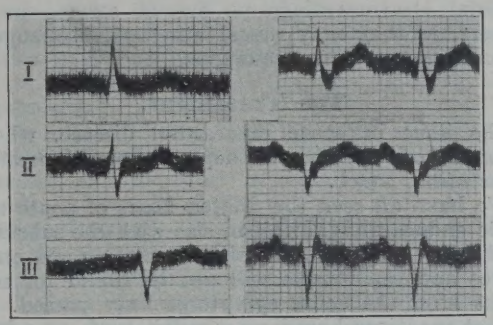
Changes in the electrocardiogram.

cardiograms developing insidiously during a period of two years before the death of the patient. Fig. 13 shows a change in the electrocardiogram of a case of angina, where health is apparently stationary.

The Prognosis.

The prognosis in myocardial disease is extremely difficult. The majority of patients die shortly after the first onset of definite symptoms of cardiac distress, some, indeed, coincidently with the first occurrence of the lesion (infarct). But some recover their health and activity in greater or less degree. One patient died at the age of 70, in full heart-block of syphilitic origin, which W. D. Macfarlane states occurred 30 years before his death. Another, as already narrated, is still at work five years after the occurrence of his first full block. Another patient who had had a partial block of insidious onset worked for nearly

FIG. 13.



2.vii.29. 12.v.30.
Changes in the electrocardiogram.

five years subsequently until his death from apoplexy. Similar records are available in cases of bundle branch block. One of our patients whose block had had a sudden onset died three years later from apoplexy, the intervening years being free from cardiac discomforts. Another, whose block had ensued simultaneously with aortic valvular disease during an attack of acute rheumatism, lived for seven years, while another patient, an alcoholic, who presented Cheyne-Stokes breathing at the time of observation with albuminuria, a high blood pressure, chronic bronchitis, and an ankylosed hip, lived for more than seven years subsequently.

The results in infarct, too, are sometimes very satisfactory. One of our patients lived for more than seven years, working hard for more than five of these years. Two others remained at work for about five years, another for four, and another still plays golf five years after his myocardial "insult" was recognised. Four at least of the cases of insidious onset lived for more than four years after its recognition, and one is still at regular work.

The lesions which are due to myocarditis, whether temporary or permanent, are perhaps the most satisfactory, though they vary as the cause is rheumatic or "bacterial," and with the probability or the reverse of a recurrence of the active process. The outlook in syphilitic cases is always hopeful as in visceral syphilis elsewhere, if appropriate treatment is possible, but too much must not be expected. The causal lesion is usually an endarteritis but occlusion of the vessel is generally due to thrombosis, which, as Gowers pointed out many years ago, is not a specific lesion, and so not amenable to specific treatment. Necrotic tissue cannot be revived. But specific treatment can open out the lumen of affected arteries in the neighbourhood, and so improve the nutrition and augment the functional activity of the parts at the periphery of the primary lesion. Atheromatous lesions cannot be dissipated, though the progress of

the sclerosis can be delayed. But it has been clearly shown by many observers, and recently by Campbell with injected hearts, that, given time, extremely efficient anastomotic developments are possible, particularly if the process of the narrowing is slow, a conclusion which has been corroborated by many clinical observers. The danger of sudden death, however, remains.

Serial electrocardiograms are of service in this respect, as they may reveal progressive changes or a continuance of the status quo.

The Treatment.

The issue in acute myocardial disease, whether inflammatory or ischæmic, depends upon *the treatment of the initial attack.*

We have all seen the dilated heart of acute rheumatic endocarditis shrink in size with the subsidence of the fever and the arthritis, but the scars on the valves and the muscle will not be sound for many weeks after the acute symptoms have passed. We cannot predicate how long it will take for resolution to be complete, for we know that in pneumonia, for example, the rate of resolution of the lung varies greatly from causes of which we are seldom cognisant. The only safe plan is to play for safety and maintain rest for several months after the acute symptoms have passed. We keep these rheumatic patients in bed for at least two months after the pulse-rate and the temperature have returned to normal, and even for a longer period if the patient's general health does not seem to be restored.

A similar line of treatment affords the best results in infarct. The rest *must* be absolute at first. We have known several patients die on the night stool, and more have serious syncopes. Restlessness must be combated by sedatives, and by opium if necessary. Rest in this case, also, must be continued for many weeks.

The chronic cases of insidious origin are more difficult to treat, but here, again, we have had satisfactory results from an initial rest in bed for several weeks, thus permitting anastomotic developments to proceed before throwing any undue strain upon the affected muscle. Massage of a mild kind is often useful at this stage. When exercise is again permitted care should be taken that it is never of such a kind as produces *any* discomfort, the patient being warned not to fight his troubles, but to learn how to circumvent them. The need for an amyl capsule should be prevented by the common-sense accommodation of the patient's desires to his limitations.

A syphilitic origin indicates specific treatment; while every effort should be made to improve the general nutrition and to maintain the value of the blood, particularly if the channels of the blood stream are narrowed. Symptoms of cardiac failure require treatment of the usual kind.

We have great pleasure in acknowledging the kindly assistance of many friends; in particular, J. L. Anderson, G. B. Fleming, A. S. Henderson, J. A. MacWilliam, W. D. Macfarlane, J. Muir, W. T. Ritchie, W. Roxburgh, J. F. Somerville, A. Tindal, and Farquhar Macrae.

A NOTE ON THE METABOLISM OF TUMOURS.

BY F. DICKENS, M.A. CAMB., PH.D. LOND.,
WHOLE-TIME WORKER FOR THE MEDICAL RESEARCH COUNCIL;
AND
F. ŠIMER, M.D.,
CLINICAL ASSISTANT, UNIVERSITY OF BRATISLAVA, CZECHO-SLOVAKIA,

(From the Courtauld Institute of Biochemistry, the Middlesex Hospital.)

FOR many years a search has been made to find some differences between the chemical changes occurring in normal and malignant tissues which might throw some light on the problem of tumours. Are there any chemical reactions characteristic of tumour tissue which may distinguish it from normal body tissues? Of the many attempts which have been made from time to time to answer this question, at present there appears to be only one striking series of discoveries which may be regarded as firmly established. These have resulted from the work of Otto Warburg and his collaborators.[1]

This group of workers has devised specially sensitive methods for studying the metabolism of isolated tissues in vitro, as a result of which they were able to show that the metabolism of the tumour cell is made up of two distinct phases: (1) respiration; (2) glycolysis—i.e., the breakdown of sugar into lactic acid *without* consumption of oxygen.

Very soon after the discovery by Otto Warburg of glycolysis by tumour tissue, it became clear that the property of glycolysis is widely distributed among animal tissues. In the absence of oxygen all animal cells produce lactic acid from carbohydrate, though different types of tissue produce different amounts. Most adult tissues glycolyse to a very limited extent, but rapidly growing cells of all kinds, including tumours, have a high glycolysis, and broadly speaking the more rapidly growing the tissue the greater the amount of lactic acid produced. An important distinction arises when the glycolysis under aerobic conditions is examined. For some time it appeared probable that the characteristic of malignant growth was that the respiration of tumour tissue was too small to prevent the appearance of lactic acid. Consequently, tumours produce very large amounts of lactic acid even under aerobic conditions, whereas the embryo has little or no aerobic glycolysis. Benign tumours were found to occupy a position intermediate between malignant and normal growth. Their respiration is sufficient to lower the aerobic glycolysis to some extent, but there is a fairly large production of lactic acid aerobically.

Later work made it clear that this classification was untenable. Many important cases of malignant tumours with a high respiration have been recently described. The effect of this high respiration on glycolysis is very variable. In some examples —e.g., some of the spontaneous mouse tumours studied by Murphy and Hawkins [2]—it caused the complete disappearance of aerobic glycolysis. In

other instances in spite of the large respiration the greater part of the glycolysis persists aerobically. A number of interesting articles of this have been carefully studied by Crabtree [3] and confirmed by Warburg.[4]

In order to reconcile these diverse facts it is necessary to make certain assumptions which do not appear at present to be quite satisfactory. In particular, it is necessary to postulate that in some tumours, however large the respiration may be, it has lost the power normally present in all tissues of removing a definite amount of lactic acid. During an investigation by us of tissue metabolism, the detailed account of which is in the course of publication, some important new facts appeared which are intimately connected with the general aspects of this problem. Those points of our investigation which have a direct bearing on the problem of tumour metabolism are briefly recounted below.

Oxidative Metabolism of the Tissues.

Whilst glycolysis is concerned solely with carbohydrate the same cannot be said of the oxidative metabolism, which is in many cases divided between carbohydrate, fat, and protein. The questions which we set out to decide were (*a*) what is the proportion of carbohydrate used in oxidation by various normal and tumour tissues? and (*b*) does the proportion of carbohydrate used in oxidation bear any relationship to the known power of the tissue to form lactic acid from carbohydrate?

It has not previously been possible to give any decisive answer to these questions, because for technical reasons suitable methods for the sufficiently accurate measurement of respiratory quotient in highly glycolysing tissues were lacking. A method has now been arrived at which has enabled us to determine the respiratory quotient (R.Q.) in normal and glycolysing tissues with a maximum error of 0·02. By the application of this technique the above questions can be answered with considerable exactness.

Normal Tissues.—In a series of normal tissues examined by this method the value of R.Q. showed a definite and consistent relationship to the value of anaerobic glycolysis determined under similar experimental conditions. This is at once evident from the figures given for normal tissues below. In this Table the value of the R.Q. is compared with the measurements of lactic acid formed per hour anaerobically, the latter being expressed as a percentage of the dry weight of the tissue. All the values in this Table represent the mean of a number of determinations, all of which were consistent. Hence in normal tissues the increase in the ability to oxidise carbohydrate, as shown by the increasing value of the R.Q., runs parallel to the extent of anaerobic breakdown of sugar to lactic acid by the various tissues.

T.	R.Q.	A.L.A.	T.	R.Q.	A.L.A.
Liver	0·78	1·2	*Crocker sarcoma (mouse)**	*0·88*	*8·7*
Kidney	0·86	1·2	*Spindle-cell mouse tumour**	*0·91*	*9·0*

Embryo	1·04	3·5	*Jensen sarcoma*	*0·83*	*14*
Spontaneous mouse tumour I.	*0·87*	*6·4*	Retina	1·00	35
Slow growing sarcoma	*0·94*	*7·0*			
Chicken embryo	1·00	7·3			
Brain cortex	1·00	7·6			
Spontaneous mouse tumour II.	*0·91*	*8·2*			

T. = Tissue (rat tissues unless otherwise stated). R.Q. = Respiratory quotient. A.L.A. = Anaerobic lactic acid per cent. of tissue weight per hour.

* We wish to express our thanks to Dr. J. A. Murray, F.R.S., Imperial Cancer Research Fund, for these tumours.

Tumour Tissue.—If the figures given in italics in the Table are now considered, it will be observed that the values for the R.Q. of tumour tissue are always definitely below unity in the fairly representative collection measured up to date. All the tumours formed very large amounts of lactic acid anaerobically.

It therefore follows that in spite of the high *anaerobic* catabolism of carbohydrate, the ability to oxidise this foodstuff is definitely defective in tumours.

Human Tumours —The majority of human tumours, unlike the tissues reproduced in Table I., contain variable proportions of tumour cells mixed with normal tissue and rarely approach the high content of tumour cells found in transplanted tumours. Consequently, the lactic acid produced per unit weight of tissue is less than for the tumour tissues in Table I. The figures are therefore not included in the above Table, but two examples are given below, from which it will be seen that the same abnormally low respiration of carbohydrate occurs.

Human Tumours.	R.Q.
Carcinoma of breast	0·84
Papillocarcinoma of bladder	0·87

Discussion of the Above Table.—Considering first the normal tissues, our results do not support the apparently somewhat prevalent view that most normal tissues when given a sufficient supply of sugar utilise mainly carbohydrate. On the contrary, a number of normal tissues have, under these conditions, a mixed oxidative metabolism. These are the tissues with low anaerobic glycolysis. On the other hand, all highly glycolysing normal tissues have a carbohydrate respiratory quotient. This group includes retina, which has proved a serious exception to all previous attempts to classify animal tissues on the basis of their metabolism.

The correctness of Bohr's hitherto unconfirmed observation, made in 1900, that the embryo has a quotient of unity is proved by the above experiments. In general, therefore, young growing normal tissues are distinguished from most adult tissues by (*a*) their high anaerobic glycolysis, and (*b*) their high respiratory quotient. In other words, normal growing tissues have a high carbohydrate metabolism, not only in the absence of oxygen but also aerobically.

Turning to the metabolism of tumours, it will be seen from the above classification that their position is definitely abnormal. Their rate of growth and their glycolysis resemble that of the embryo, whilst their respiratory quotient is that of the adult tissues.

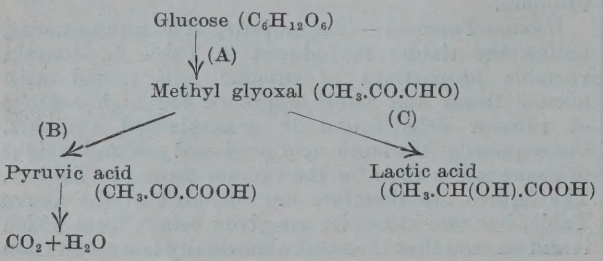
This investigation is now being extended to other representative types of pathological growth. This is obviously necessary before it can be stated how far this defective oxidation is limited to malignant tumours. We have, however, obtained some indication that similar metabolic damage may be associated with certain other types of pathological growth.

Nature of the Defective Oxidation.

These facts show that in tumours the oxidation of carbohydrate is damaged in some way, whilst their anaerobic metabolism is unaffected. The question

arises as to what is this defect in the oxidation in tumours. In view of the fact that the insulin content of tumours has been shown to be low in comparison with that of most normal tissues,[5] one might expect that this fact might give a clue to a possible solution of the problem. However, the part taken by insulin, if any, is in this case not a simple one, since the addition of insulin to isolated tumour tissue does not affect its oxidative metabolism to a measurable extent.

It is impossible to carry the analysis of the oxidative defect in tumours further without considering the intermediary metabolism involved in glycolysis and respiration. The question is a difficult one, but probably the reactions shown in the following simplified scheme are of importance.



According to this scheme, from which many stages not essential for the present discussion have been omitted, the molecule of hexose is first split into two molecules of triose—very probably methyl glyoxal or its hydrate. In the absence of oxygen this three-carbon chain is not broken down further, but appears as lactic acid. In oxygen, a part of the triose is oxidised via pyruvic acid, finally to CO_2 and water.

Two types of carbohydrate metabolism may now be distinguished on the basis of our measurements.

Type 1.—The velocity of the changes in stage A controls the carbohydrate metabolism—aerobic and anaerobic. This is the case of normal tissue with low glycolysis and consequently low R.Q.

Type 2.—The velocity of the changes occurring in stage B is diminished. In this case a high glycolysis indicates the unaffected course along routes A and C, whilst a low value of R.Q. indicates damage to the reactions occurring by route B. This is the case in tumour tissue.

Support for this theory is given by three further important facts which the method used enabled us to establish with certainty. (1) Addition of lactate to the medium causes an increase in the respiratory quotient of tissues of type 1 (e.g., liver). Hence tissues belonging to this group can utilise metabolites having a three-carbon chain. (2) Addition of lactate to tumour tissues causes no change in the R.Q. (3) Addition of pyruvate to either normal or tumour tissue causes an increase of the R.Q. to over unity (theoretical R.Q. for pyruvic acid = 1·20). Hence both types of tissue can attack pyruvate, and in the case of tumours the break in the oxidative route B must occur between the methyl glyoxal and pyruvic acid.

Summary.—There is a definite deficiency in the oxidation of carbohydrate by tumour tissue.

REMOVAL OF NON-MALIGNANT TUMOURS OF THE BREAST.

By H. H. Greenwood, M.B., B.S.Lond., F.R.C.S. Eng.,

CONSULTING SURGEON TO THE GREAT WESTERN RAILWAY HOSPITAL, SWINDON.

The operation devised by T. Gaillard Thomas (sometimes called "plastic resection of the breast") for the removal of so-called "innocent" tumours of the breast deserves to be more universally employed.

Breast tumours displaying the stigmata of malignancy receive an appropriate radical extirpation, and to the technique of the operation anxious care is lavishly given. Those of known innocence, such as true adenomata or lipomata, are often removed without any consideration being bestowed on the psychological and æsthetic aftermath, which is left as a perpetual legacy to the patient. Even those, such as a cystic "mastitis," in which there is merely suspicion without real evidence of malignancy, may well be conceded a little more indulgence in the planning of the operation. Binnie [1] declares that in these cases the patient should "receive the benefit of the doubt and radical measures adopted"—that is, should be condemned to the radical operation forthwith. This counsel seems harsh and precipitate, ignoring the extremely severe character of the modern radical operation. A tumour which displays no evidence of malignancy on careful examination before the operation seldom shows sufficiently marked evidence, tactile or visual, during the course of the operation to warrant an immediate radical operation. The early or precancerous stage is detected only after careful microscopic examination by the pathologist, not by a hasty and cursory inspection during the course of the operation. The issues are too serious, the implications of the decision too far-reaching, for such cavalier methods. A cancer at so early a stage as to defy a careful physical examination beforehand will gain little further deadliness by the postponement of the radical operation for the few days necessary to establish a sure diagnosis by pathological examination.

In recent years fewer examples seem to occur of the enormous cysto-adenoma, neglected and allowed to progress until the whole of the mammary gland with its fatty envelope is hopelessly destroyed. A gross example would conceivably preclude any attempt to preserve even a ghostly image of the normal organ, and would compel an "amputation." So, too, those rare conditions of a progressive and destructive nature, such as tuberculosis, actinomycosis, and possibly gumma, demand effective extirpation of the whole organ, together with the overlying skin. Cosmetic considerations must yield to the necessities of the case, and usually a free removal by a lenticular incision is imperative. There remains a large class, including the simple adenoma, the so-called "interstitial mastitis," and intracanalicular fibro-adenoma, in the removal of which other considerations than the mere curing of the disease may well receive closer attention.

The adenoma, being an encapsuled tumour, can be effectively removed by a crescentic incision on the lower and outer margin of the breast, the whole organ being turned over and the tumour shelled out, after which the breast is replaced in its normal position and the wound sutured. An excellent description of this operation is given by Bickham,[2] the

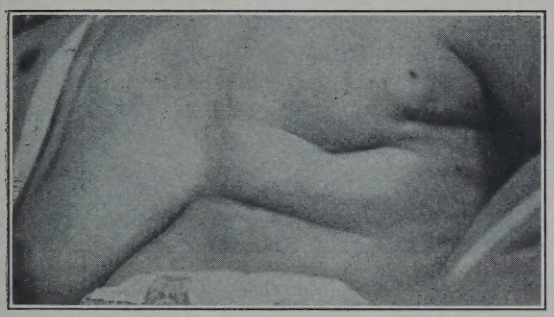
description following the account of the original operation devised by Gaillard Thomas and afterwards practised by J. C. Warren.

Chronic Mastitis.

Most of the cases calling for limited removal of the mamma are cases of "interstitial mastitis" or, more correctly, "desquamative epithelial hyperplasia" (Cheatle).

Unfortunately the convenient term "chronic mastitis," admirably terse and descriptive, is inaccurate. The

FIG. 1.



The result of an operation done several years ago for a simple tumour of the left breast in a young married woman; I was consulted as to the possibility of effecting some mitigation of the distressing deformity inflicted. For such cases Gillies [23] has devised an ingenious plastic operation.

deductions of Lenthal Cheatle from his searching investigations into the pathology of the disease have received general acceptance, but the nomenclature that he suggests [3] has proved too cumbersome to pass into current literature. In his Hunterian lecture Geoffrey Keynes [4] reviewed the evidence and showed that chronic mastitis, fibro-adenoma, simple cyst, and galactocele have in common these histological changes: "round-celled infiltration (lymphocytes), fibrosis, dilatation, epithelial changes of two kinds (desquamative and proliferative), and formation of papillomata." He gives good reasons for believing that these so-called diseases are merely manifestations of the same underlying pathological processes. It seems impossible to devise a nomenclature that will be accurate and fully descriptive, and it would simplify our conception of these diseases if they were grouped together under one title. "Hyperplastic disease of the mamma" would have the merit of being, so far as it goes, more accurate than mastitis. There is, indeed, much to commend the plan of labelling a disease of which the pathology is obscure or the manifestations protean by the name of one who has advanced our knowledge of it. There is possibly as much warranty for the title "Cheatle's Disease" as for that of Köhler, Banti, Legg, or Schlätter. It is curious that the term mazoplasia, suggested to Cheatle by Rolleston in 1924, has not passed into current use.

Whilst awaiting a solution of this debatable but comparatively minor problem, we can realise that there are certain features about this group of interesting diseases, alike at least in their innocence and in their inability to transgress the limits of the corpus mammæ, which have a bearing upon the operation designed to effect a cure.

In so far as operative treatment of a tumour of the breast is concerned, the growth is either malignant or innocent. If it be innocent, complete removal without fear of recurrence can be achieved with certainty and ease, and there only remains for decision the method that confers on the patient the least degree of mutilation.

The vicissitudes of belief regarding the pathology of the disease mazoplasia is evidenced by the rich but chaotic terminology quoted by Parker Syms.[5] Of the 11 variants which he gives, that of Sir Astley Cooper, "chronic mammary tumour," is the most satisfactory, being descriptive and non-committal. Acute divergence of opinion as to the presence of inflammation has existed; whereas Syms [6] declares "the disease is undoubtedly primarily an inflammation," Grant [7] shrewdly observes that "the gross appearance and symptoms at menstrual periods and during lactation savour far more of an inflammation or mastitis than do those seen in an average case of chronic mastitis," and concludes that the disease is an abnormal epithelial hyperplasia. An interesting observation by Rutherford Darling [8] is that "oöphorectomy leads to atrophy and to changes (in the breast) identical to those met with in chronic mastitis."

Similarly, there is disagreement as to the frequency with which cancerous changes can be detected in mammæ removed for mastitis; for whereas Bloodgood [9] examined 222 out of 350 mastitis cases at Johns Hopkins Hospital and declared that "not one showed evidence, gross or microscopic, of carcinoma," Ewing [10] states that "50 per cent. of breasts excised for cystic disease show pronounced precancerous changes or miniature carcinomas." Between these extremes we find: [12]

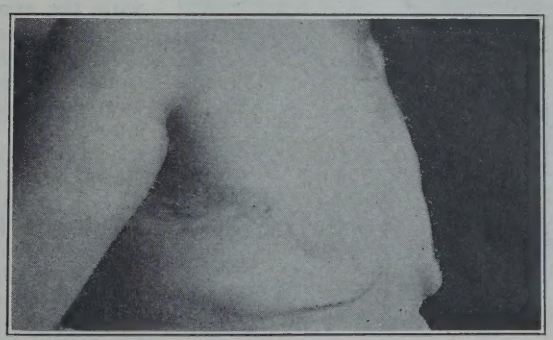
	Per cent.		Per cent.
Greenough and Hartwell	10	Lockwood	20
Warren	13	Finney	10–50
Verga (5 in 28)	18	Lahey[11]	10–50

Bloodgood,[13] however, adds that in 3 out of 128 where partial removal of the breast had been done carcinoma developed later. In my series there were 3 out of 60 cases—i.e., 5 per cent. It seems established that, when malignant changes do occur, the site may be at any point from the ampulla of the duct to the most distant acinus of the corpus mammæ—at any part of what may be termed the mammary tree.

Surgical Anatomy.

The female mamma consists of the true breast tissue—namely, the acini with their ducts (conveniently referred to as the corpus mammæ) encased in its fatty envelope (Stiles [14]). The approximate limits are from the second to

FIG. 2.



The result of an operation for "mastitis" in both breasts done at a large general hospital in London for a nurse who was then aged 21; a sensitive woman whose subsequent married life has been embittered by the (? unnecessary) mutilation.

the seventh rib vertically and from the edge of the sternum to the midaxillary line laterally; Spence's axillary tail runs up towards the axilla as high as the third rib. Stiles [15] also taught that the corpus mammæ is so intimately connected with the fibrous framework that the two cannot be separated, so that there is no capsule proper; the fibrous stroma is so broken up and branched at its periphery that it becomes directly continuous with the connective tissue framework of the fatty superficial tissue. The disposition of the fibrous scaffolding is beautifully portrayed in some of the older text-books.[16 17 18] In addition to the well-known suspensory ligaments of Cooper, fibrous processes pass from the deep surface of the gland to the pectoral fascia, sometimes even into the pectoral muscle, carrying with

them minute lobules of the gland. In the parous mamma at the end of lactation involution occurs, the corpus mammæ shrinks, and fat becomes deposited superficially and also on the deep aspect of the gland.

The blood-supply of the gland is derived from: (1) The second, third, fourth, and fifth perforating branches of the internal mammary. (2) Descending branches from the acromio-thoracic axis. (3) The principal supply comes by way of the long thoracic or external mammary branch of the axillary artery. (4) Small branches from the intercostals.

As each artery of supply approaches the margin of the gland proper it divides into two sets of branches, the one coursing superficially through the fatty envelope towards the nipple, and the other passing deeply into the substance of the corpus mammæ. This disposition, well seen by transillumination, influences the choice of the ideal incision for the operation of mastectomy—a term suggested by Grant.

The nerve-supply comes from: (1) Descending cutaneous branches of the cervical plexus. (2) Lateral and anterior branches of the second to the sixth intercostal nerves. (3) The gland itself (sensation), from the perforating terminal branches of the fourth, fifth, and sixth intercostals.

In addition there is probably a free supply of sympathetic nerves of whose course and origin nothing appears to be known, although it is highly probable that they follow the course of the arteries supplying the gland.

Operation.

For non-malignant tumours of the breast the operations necessary may be divided into three classes.

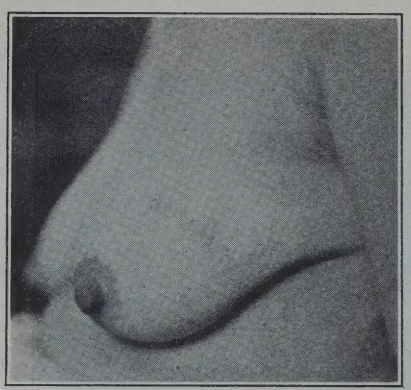
1. Actinomycosis and tuberculosis demand amputation with removal of the overlying skin, treating the disease as locally malignant.

2. Large innocent tumours such as advanced (so-called) cysto-adenoma and hydatid disease, where the whole corpus mammæ, together with its fatty envelope, has been destroyed, require a lenticular incision with preservation of as much of the overlying skin as is possible.

3. The majority (adenoma, fibro-adenoma, serous cysts, mazoplasia) need Thomas's operation and observation of the strictest conservation.

My interest has been centred on the last class and on the technique necessary to ensure the best cosmetic result compatible with the cure of the disease. "The operation is perhaps the easiest in surgery" (Binnie[1]). Considering the blood-supply, it is evident that the ideal site for the incision is in the lower hemisphere of the breast, and this corresponds with the site of election for cosmetic considerations. The incision advised by Warren[19] and recommended by Bickham falls upon the sulcus along the lower and outer circumference of the breast, whereas Fitzwilliams[20] says "I much prefer an incision extending well below the breast, whereby the breast is turned upwards and inwards, to that recommended by Warren, which was almost altogether on the outer side."

FIG. 3.



The result in a married multipara, a case of mastoplasia, aged 29. The scar has been marked with Indian ink.

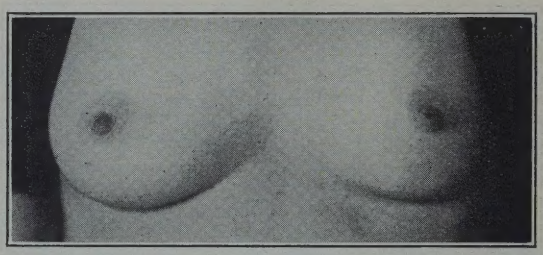
I have used both these, but find good reasons for the adoption of a crescentic incision through the skin over the lower and outer aspect of the breast itself about half an inch from the line of the sulcus. These reasons are:—

1. The skin is healthier and the resulting scar more nearly "invisible." Even a trivial low-grade sepsis, not infrequently regarded as negligible in wounds accounted "clean," mars the quality of the scar.

2. The main trunks of the arteries escape severance and the nutrition of the tissues that are left is more vigorous, so that there is less post-operative shrinkage and distortion. This applies specially to the nipple, which has been known to slough from lack of blood-supply—a mischance that has not, however, befallen any of my cases.

3. Greater accessibility to the upper and internal portions of the corpus mammæ, where outlying lobules are apt to be overlooked.

FIG. 4.



An unmarried girl of 24, from whose left breast an adenoma in the lower outer quadrant was removed.

In whatever part of the breast, then, the tumour may be, a crescentic incision is made on the skin of the breast itself, with its centre in the lower and outer quadrant; scratches are made at right angles to the line of the proposed incision to ensure accurate coaptation of the skin edges afterwards. The scalpel should be of the sharpest. The incision is deepened until the breast tissue proper is reached and then, keeping close to the corpus mammæ and preserving every scrap of fibrous tissue and fat, the lower margin is defined and the whole breast turned over, upwards and inwards in the way originally described by Thomas.

At this stage the enucleation of an encapsuled tumour (e.g., an adenoma) is done through a radial incision in the deep aspect of the corpus mammæ, but in the majority of cases of mastitis or mazoplasia it is necessary to remove the whole corpus mammæ. On the deep surface of the gland, especially in parous subjects, there is sometimes a thin layer of fat, which should not be removed. Occasionally, however, there is found a lobule of the gland which lies deep to the fascia covering the pectoral muscles, embedded in the muscle and connected to the main corpus mammæ by a narrow isthmus only. Unless the breast is turned over carefully such an outlying lobule may be left behind.

The most meticulous care is necessary in dissecting away the anterior surface of the gland; interlobular tongues of fat should not be sacrificed, nor the fibrous ligaments of Cooper, along which vessels and lymphatics run. The strand of tissue between the nipple and the corpus, consisting of the main ducts, is carefully isolated and severed close to its junction with the corpus mammæ.

Arrest of hæmorrhage should be very complete and achieved without including in the ligature a mass of surrounding tissue. Since the vessels are severed close to the gland the bleeding points are numerous, at least five or six on the inner side from the perforating arteries, two or three small branches from below derived from the intercostals. about three on the outer side from the external mammary, and two or three above from the acromio-thoracic.

A purse-string suture of fine catgut is often necessary to ensure eversion of the nipple, and a few sutures

sometimes help to refashion the fatty and fibrous remains in the image of a normal breast. A small 24-hour drain is sometimes advisable. The skin requires accurate and gentle suture with fine fishing-gut, and here we may keep in mind Lord Moynihan's [21] words.

"The cleaner and the gentler the act of operation the less the patient suffers . . . . the more exquisite his healed wound, and the happier his memory of the whole incident. . . . . The appearance of a wound is often the best index to the quality of the work that has been done throughout the operation."

To ensure the best scar, stitches should be removed on the fifth or sixth day.

PRESERVATION OF THE NIPPLE.

The psychological and æsthetic importance of the nipple to a woman is not readily appreciated by the masculine mind. Reduction in the size of the mamma, especially if the characteristic contour can be retained, she bears with equanimity, but the nipple is a sign-manual of her sex and spares her the stigma of "mutilation." Moreover, in the removal of non-malignant tumours, sacrifice of the nipple is more than undesirable—it is quite unnecessary. Tumours proper (e.g., adenomata) never involve that portion of a main duct which lies distal to the ampulla and which, traversing the nipple, is lined by squamous epithelium. The cysts of mazoplasia sometimes occur first below the musculature of the nipple but none within the nipple,[22] and are never so close to the surface as to involve ablation of the nipple. The cysts arise mainly from the portion of the ducts which lies between the ampullæ and the acini, rarely from the ampullæ themselves. The stretch of duct reaching from the surface to the ampulla can therefore be preserved with safety in all cases. It is noteworthy that the nipple thus left never becomes unduly sensitive, nor has the nutrition of the part ever been jeopardised in any of my cases.

Palliative Treatment.

The fundamental condition in so-called chronic mastitis has been shown by Lenthal Cheatle to be a "desquamative epithelial hyperplasia." Whether the formation of cysts is an inevitable ultimate sequel, certain it is that in a considerable percentage gross cysts do eventually develop, and in these cases palliative treatment can do little more than mitigate the severity of the pain. For the most part they are fated to come to operation, or to bear the penance of constant pain and dread of malignant disease. Nor does palliative treatment influence appreciably those complicated by the presence of adenoma or fibro-adenoma. There remains a residuum of early cases in which certain measures appear to arrest the pathological process and to dispel the disquieting symptoms.

The 60 cases recorded were treated between 1921 and 1929 and most were given a short course of treatment before operation was discussed. Even when operation is inevitable, a preliminary course of treatment serves to satisfy the patient that the dreaded operation is not being lightly undertaken. In a large number of cases, not recorded, perseverance with palliative measures sufficed to bring about a symptomatic cure and operation was unnecessary. The measures which have proved useful are the following:—

1. Inunction with iodex and radiant heat for 20–30 minutes proved efficacious in many cases.

2. Ultra-violet ray treatment (2 minutes increasing to 15 minutes) appeared to do good in some cases.

3. Hot bathing followed by centripetal massage often causes great relief of pain and diminution in the size of the tumour.

4. A mercurial ointment occasionally soothes pain and appears to diminish the swelling—*ung. hydrargyri* or *ung. hydrargyri oleatus*.

5. X ray treatment may be expected to arrest the morbid process, but the analogy with carcinoma is not sufficiently close to warrant high hopes. In a recent case, however, relief from pain has certainly been achieved. (? suggestion.)

6. In all cases firm bandaging or support by a well-fitting brassière is advantageous.

7. Probably the most efficacious weapon will be found in sun-baths. Only in a few of my cases has it been practicable to secure this, but in each case the benefit was unmistakable. It is said that in countries where women habitually wear no clothing above the waistline the disease is unknown; such a sweeping generalisation must be received with caution but my limited experience tends to confirm it.

Analysis of Cases.

1. The conservative operation as outlined above has been done in 50 out of 60 cases recorded for non-malignant tumours of the breast; in the remaining ten amputation was done. 2. The youngest patient was 20 years old and the tumour was a "fibro-adenoma." 3. The youngest case of mazoplasia was 23 years, the oldest 63 years. 4. Only five out of 60 were unmarried. 5. In every case over the age of 45 and in most of the others the whole corpus mammæ was removed; 12 of the 60 cases had a segment only of the gland removed, but of these three were cases of adenoma. 6. Forty operations were done on the left side, 21 on the right side; one case required removal of both breasts. 7. In the 50 conservative operations the nipple was preserved in every case and in none of these was there any untoward consequence. 8. The average age was 42·3 years. 9. The results are almost uniformly good. Sometimes a neuralgic pain, usually trivial, is complained of along the course of the descending branches of the cervical plexus, or sometimes along the distribution of the intercostohumeral. These pains are more common amongst the cases of mazoplasia in which a segment only of the gland has been removed, and the impression grows stronger that in this disease it is always the wiser course to remove the whole of the corpus mammæ. 10. In two cases the pathologist's report was "duct-carcinoma." In both these the radical operation was done later (1927 and 1928) and in both there is no sign of recurrence. In a third case the report was "carcinoma." The patient declined the radical operation and had a prophylactic course of X ray treatment. Nearly two years have elapsed without any evidence of recurrence or metastasis.

EXPERIMENTAL OBSERVATIONS ON THE ACTION OF RADON ON THE SPINAL CORD.*

BY HUGH CAIRNS, M.B. ADEL., F.R.C.S. ENG.,
ASSISTANT SURGEON TO THE LONDON HOSPITAL:
AND
J. F. FULTON, D. PHIL. OXF., M.D. HARVARD,
FELLOW OF MAGDALEN COLLEGE, OXFORD.

(From the Laboratory of Physiology, Oxford, and the London Hospital.)

EXPERIMENTS designed to determine the maximum dosage of radon that might be applied safely to malignant tumours of the central nervous system have disclosed a striking relation between the dose of radon and the time of appearance of symptoms of destruction of nervous tissue. Cats and monkeys were employed, and the spinal cord was selected for investigation since symptoms of its destruction can be quickly recognised; symptoms that follow destruction of the higher regions of the central nervous integration are not so easily observed, and are difficult to interpret.

Radon seeds of varying doses, but always 1·5 cm. long and screened by 0·3 mm. of platinum, were placed, with aseptic precautions, alongside the spinal cord in the lower dorsal region. This preliminary communication and the Table that follows are based on experiments in which the seeds were implanted outside the dura. The animals were carefully observed during the two or three weeks after operation, and several were studied for a period of four or five months.

One animal showed weakness of a hind extremity immediately after operation, and this was discarded, as the cord had undoubtedly been injured while the seeds were being inserted. In every other instance during the first 24 hours after operation there was no sign of weakness of the hind limbs or of loss of sensation. With an overwhelming dose of radon (e.g., 31 millicuries) signs of weakness of the hind extremities appeared 30 hours after operation. Except for loss of position sense no sensory disturbance could be detected at this time. The paraplegia always became complete three to four days after the onset of the first symptom, even though in some experiments the seeds were withdrawn 48 hours after they had been inserted. When smaller doses of radon were used the time of onset of the first symptom was later, and the appearance of complete paraplegia was correspondingly delayed. In cats any dose greater than 9·5 mc. produced complete paraplegia; with a dose of 9 mc. or less the paraplegia was incomplete or slight; and with doses of 4 mc. or less there were no obvious neurological symptoms at any time. Monkeys proved more resistant than cats, for a dose of approximately 12 mc. produced only slight weakness. The following Table gives a summary of our results.

The first symptom displayed by the animals after insertion of the radon was loss of position sense. This sometimes preceded by several hours the appearance of definite motor weakness. The animals invariably passed through a stage of extension before developing a characteristic complete flaccid paraplegia (in flexion), which was not unlike the paraplegia in flexion seen in human beings several weeks after a complete transverse lesion of the spinal cord. In two instances the animals remained permanently in extension and in these subsequent histological examinations showed that the dorsal quadrants were destroyed while the ventral regions remained largely unaffected.

Table showing the Effect of Increasing Doses of Radium Emanation upon the Spinal Cord (Applied Outside the Dura). Screening 0·3 mm. Platinum.

C.D.(M) = Corrected dose (millicuries).
W.K. (d) = Weakness (days).
Pp. = Paraplegia (comp., complete; incomp., incomplete).

C.D.(M)	W.K.(d).	Pp.	C.D. (M)	W.K. (d).	Pp.
	Cats.			*Cats.*	
31·3	1+	Comp.	6·6	6	Slight.
28·8	2	,,	6·3	6–8	,,
27·0	2	,,	3·7	None.	None.
24·7	4	,,	3·1	,,	,,
16·2	2–3	,,	2·8	,,	,,
16·3	4	,,	0·0	,,	,,
10·0	5	,,			
9·8	5	,,		*Monkeys.*	
9·2	5	Incomp.	11·8	3	Slight.
9·0	4	,,	9·0	None.	None.
7·3	8	Slight.	6·1	,,	,,

In these experiments the radon seeds were applied to the dorsal surface of the cord, and the destruction proceeded in a ventral direction, the posterior columns being affected first and the ventral tracts last. We believe that the period of extension is one in which the posterior columns and possibly other structures in the dorsal quadrants of the cord are impaired while the ventral quadrants are normal. Further work is being done on this problem. Full details concerning the pathological character of the lesions and the degenerations will be published later.

We desire to thank Prof. Sidney Russ for supplying us with radon, and for his help and criticism. The expenses of the work were defrayed by the Charles Bingham Bolton Fund for Neurology.

* A paper read before the Society of Neurological Surgeons on Nov. 23rd, 1929.

RELATIVE VALUE OF VARIOUS SOLUTIONS FOR SCLEROSIS OF VARICOSE VEINS.

BY DAVID LEVI, M.S. LOND., F.R.C.S. ENG.,
ASSISTANT SURGEON, INFANTS HOSPITAL, VINCENT-SQUARE; SURGICAL REGISTRAR, ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.

THE ideal solution for injection of varicose veins has not yet been found. A list of the various solutions in common use at the present time is set out below, and the advantages and disadvantages peculiar to each are discussed.

The susceptibility of veins to a sclerosing injection varies from individual to individual, and this personal element can neither be eliminated nor ignored. My generalisations are drawn from observations on different series of patients extending over a period of four years. The total number of injections given amounts to 4000, and they have been divided into four groups according to the drug used.

FOUR SCLEROSING AGENTS.

1. *Glucose.*—Up to 5 c.cm. of a 66 per cent. solution was injected at a time. The advantages of this solution are that the substance injected is innocuous and does not cause any systematic disturbance. It produces clotting over large areas of vein, but the clot tends to be a loose one. The

treated vein is tender to touch for a period of five to six weeks ; it looks red for two weeks or more. There is a tendency for the clot to break up, and of the recorded instances of pulmonary embolus resulting from vein injection the majority have occurred following the use of glucose (Olson,[1] Levi [2]).

2. *Sodium Salicylate.* — Solutions of several strengths are used, the choice depending on the susceptibility of the vein treated. It is usual to start with a relatively weak solution and work upwards. The advantages of this substance are that it produces a limited sclerosis and causes obliteration of two or three inches of vein wall. The resulting clot is firm and incorporated with the vein. There are, however, several disadvantages attending the use of salicylate. The first is that the injection is painful and accompanied by cramps in the calves. If the injection is made into subcutaneous tissue gangrene, followed by ulceration, nearly always occurs. Sometimes the injected fluid leaks back through the puncture made in the vein wall by the needle. Even a small quantity of salicylate in the tissues will act as an irritant. Quite a large percentage of patients do not "take," and have to be given numbers of injections of increasing strengths. In at least two of my patients recanalisation of the sclerosed vein occurred within 18 months of the time of injection. Salicylate solutions go brown on keeping. Attempts have been made to overcome the cramps produced by adding local anæsthetics to the salicylate solution ; the most popular preparation is lithium salicylate with the addition of tutocaine.

3. *Quinine and Urethane.*—2 to 3 c.cm. were injected at each sitting. The quinine is the active element and it destroys the endothelium of the vein ; the urethane is added for its anæsthetic properties. The great advantage of this preparation is that it usually "takes" and consequently there are very few refractory veins, and the total number of injections is thereby reduced. It is painless at the time of injection, but there is often a complaint of cramp five to six hours afterwards, especially if the patient has been sitting for any length of time, and gets up suddenly. The pain rapidly passes. The reaction induced by the quinine is a severe one, and sometimes the whole saphenous vein will become filled with clot following one piqûre. This clot remains red and painful for six weeks or so. In a small minority of people dizziness is apparent at the time of injection, and in women some disturbance of menstruation has been observed. The tissues are very intolerant of the injection, and a slough taking weeks to separate, leaving a slowly healing ulcer, is the invariable accompaniment of faulty technique. If a thin-walled vein is injected the sclerosing action is so severe that I believe the vein wall becomes permeable and the injection leaks through. Some of the sloughs appearing three to four weeks following treatment are possibly due to this cause, and are not always the result of a subcutaneous injection.

4. *Sodium Morrhuate 5 per cent.*—This substance was used extensively years ago, and was the chief constituent of a very famous cancer "cure." It was also administered, as a 2 per cent. solution either intramuscularly or intravenously, for tuberculosis. Its main disadvantage was the thrombosis which followed the intravenous administration, and on account of this the treatment fell into disrepute. Sodium morrhuate is much less irritant than salicylate or quinine, and does not produce sloughing if injected into the subcutaneous tissues. The reaction it produces in the vein is much less severe than quinine. The injection is almost painless and the discomfort afterwards is not great. I have not seen an ulcer following an injection of sodium morrhuate. Most of the patients treated reacted to the first injection. There is not the same tendency to extensive clot formations as there is with quinine and urethane. No general toxic symptoms have been observed.

VALUE OF THE TREATMENT.

From perusal of the vast literature of this subject I have formed the following conclusions.

Mortality is due almost entirely to pulmonary embolus. McPheeters and Rice [3 4] record seven deaths among 53,000 patients, Kilbourne [5] one in 5000, and Dixon five in 5400. The risk, therefore, is small—much smaller than the operative mortality, which is 0·4 per cent. There were three main causes of the recorded fatalities : the first was the injection of veins in the presence of an acute phlebitis ; the second was the injection of a sugar solution, which resulted in three deaths, McPheeters and Rice [4] ; while the third was the use of large quantities of injection material. Hohlbaum [6] used 60 c.cm. of an iodine solution. Therefore if sugar solution is avoided, if the total bulk of chemical injected is under 5 c.cm., and if the injection is not given with coexisting acute phlebitis, the treatment appears absolutely safe. There is no recorded death from pulmonary embolus, the direct result of treatment on these lines.

Recurrence is sometimes caused by recanalisation of the injected vein. More often it is due to new varicose veins appearing. It follows operative excision in 30 per cent. of patients, but in those injected it is only 6 per cent., according to Kilbourne, and 5 per cent. according to Sicard. My figures agree more with Sicard's, though the total number of patients is small, especially when compared with that of Sicard, who had 15,000 patients and has given them 120,000 injections. Recurrence, however, is a minor complication, which may be treated by reinjection.

Chemical gangrene follows the injection of substances into the subcutaneous tissues. Payne [7] records 13 instances in 1500 patients, Higgins [8] 12 in 200 patients. That this is not always the result of faulty technique I am quite sure. Kilbourne recognises that it is sometimes due to leakage through the puncture made by the needle in the vein wall. McPheeters and Rice suggest that sometimes the injected material osmoses through a thin vein. This complication can, however, be overcome by :—

1. The use of a needle with a short bevel and a moderately small bore.
2. The withdrawal of blood before injecting the chemical.
3. The retention of the needle in the vein for a minute or two following the injection.
4. The application of a small wool pad fixed with strapping or bandage rather than the use of a collodium dressing.
5. The use of sodium morrhuate if a thin-walled vein is to be injected rather than quinine and urethrane or salicylate which produce a severe reaction in many patients.

Refractory Veins.—Angle,[9] in America, injected 10 c.cm. of a mixture of sugar and sodium chloride into one individual 25 times, and repeated the operation 27 times in another. Such persistence is to be deprecated. It is better to change one's technique if a vein does not become obliterated following one or two injections into it. It has been my experience that if quinine and urethane is used, and the injection made when the patient is in bed in the evening, the vein will be thrombosed on waking in the morning. Injection should be made with the leg horizontal in bed. No tourniquet is used, and the patient is enjoined not to move for an hour after the treatment.

This technique is only followed in patients who have proved refractory.

Pigmentation along the site of the thrombosed vein is common and sometimes permanent, but it becomes progressively less over a period of 18 months.

Contra-indications may be summarised as (1) acute phlebitis. Forestier,[10] quoted by Sutton, says that "no injection should be given for ten years following phlebitis." About half of the recorded deaths following injections have been due to this dictum having been disregarded. (2) Intermittent claudication. (3) Deep thrombosis, due to any cause. (4) Phlegmasia alba dolens (Takats [11]). General diseases, such as cardiac and renal disease, are not contra-indications except during their terminal stages. Injection is safe in pregnancy, but during the latter months it appears advisable to wait till after delivery of the child. Varicose veins of the vulva react as well as varicose veins in other situations.

I should like to thank the surgical staff of St. Mary's Hospital, Paddington, and Mr. Laming Evans, for allowing me to include observations made from their patients.

CLINICAL AND LABORATORY NOTES

TWO CASES OF GLANDULAR FEVER SIMULATING TYPHUS.*

BY MAITLAND RADFORD, M.D. LOND., D.P.H.,
MEDICAL OFFICER OF HEALTH, BOROUGH OF SHOREDITCH;
AND
J. D. ROLLESTON, M.D. OXF., M.R.C.P. LOND.,
MEDICAL SUPERINTENDENT, WESTERN HOSPITAL, LONDON COUNTY COUNCIL.

CASE ONE.

ON March 27th one of us (M. R.) was asked by a practitioner to see a girl, aged 16, who had been taken ill suddenly on March 21st, and on the 25th had had a well-marked blotchy rash which the doctor thought suggestive of typhus. The early symptoms were headache, nausea, pains in the back and legs, and a general feeling of illness. On the 27th the rash had faded considerably, but was still visible. The temperature in the axilla was 102° F. The skin also showed some bites probably due to lice. Under the circumstances it seemed advisable that the case should be regarded as one of typhus and that the patient should be removed to a fever hospital. By a coincidence, J. D. R., in connexion with a discussion on tropical typhus to be held on the following day,[1] rang up the chief office of the Metropolitan Asylums Board shortly after the case had been notified to inquire about the last cases of typhus reported in London.[2] He was, therefore, only too pleased to accept the suggestion that the case should be sent to his hospital.

On admission to the Western Hospital on March 27th the girl showed a faint macular rash on the face, chest, and abdomen. The tongue was thickly coated. Some rhonchi were heard at the base of both lungs. The patient looked ill but was quite sensible. Temperature 104° F., respirations 32, pulse 106. There were numerous lice on the body as well as in the scalp.

For the next ten days the temperature remained at a high level and then began to assume an intermittent type which persisted until April 27th, when a normal level was finally reached. The patient was at first very drowsy and difficult to rouse but remained sensible and showed no signs of delirium. For a few days she suffered from retention of urine. The diazo reaction in the urine was persistently negative.

The true nature of the illness was not suspected until April 12th, the twenty-fifth day of disease, when the glands in the posterior triangle of the neck became enlarged and painful, and four days later enlargement of the axillary and inguinal glands was detected and a slight increase in size of the spleen. The possibility of glandular fever then first suggested itself and a specimen of the blood was sent to Dr. J. E. McCartney, Director of Research and Pathological Services, M.A.B., who made the following report:—

"Differential count: polymorphs 34 per cent.. large lymphocytes 56 per cent., small lymphocytes 9 per cent., large mononuclears 1 per cent., eosinophils and mast cells nil. The above results show that there is a relative increase in the number of lymphocytes, particularly the large lymphocytes, some of which have a few small red granules in the protoplasm. The polymorphs show signs of immaturity. There is hardly a multilobed cell to be seen, and in many the nucleus is merely horse-shoe shaped. One or two neutral myelocytes were seen. The red cells vary in size, but there is no poikilocytosis. One nucleated red cell was seen. No punctate basophilia was observed. No parasites—i.e., spirochætes or malaria organisms—were seen. The total cell count is not known but the blood picture shows the appearance of a case of acute glandular fever (infective mononucleosis)."

The total white cell count was subsequently found by Dr. L. J. M. Laurent to be 8320 per c.mm. The following examinations of the blood were also made by Dr. McCartney on March 29th.

Weil-Felix reaction with *proteus* X 19 "H" strain negative. Widal reaction negative to *B. typhosus*, *B. paratyphosus* A and B. Wassermann reaction ++.

Subsequent examination of the blood on April 1st and 7th for the Weil-Felix and Widal reactions yielded the same result, and the Wassermann reaction of the blood examined on April 7th was again ++. A culture of the blood taken on April 1st showed after 24 hours' incubation a growth consisting of a Gram-negative bacillus of the coliform type and a small Gram-positive cocco-bacillus of the diphtheroid type. Neither of these organisms were identified as belonging to any of the pathogenic groups and were therefore regarded as contaminants. The Wassermann reaction was performed for the third and last time on May 13th and was still found to be ++.

CASE TWO.

The patient's mother, a woman aged 36, was taken ill with somewhat similar symptoms on March 26th and

* These cases were mentioned in THE LANCET last April (1930, i., 834 and 936) under the heading of Infectious Disease in England and Wales.

[1] Proc. Roy. Soc. Med., 1930, xxiii., 1030; See also THE LANCET, 1930, i., 750.

[2] See THE LANCET, 1928, i., 1224.

was sent to the Western Hospital on April 3rd as a case of typhus.

On admission she presented a faint mottling of the chest and abdomen. There were signs of bronchitis. The patient was very deaf but was quite sensible. Temperature 103·4°, pulse 104, respirations 30.

The clinical and hæmatological picture in this woman was very similar to that of her daughter. The temperature at first kept high and then assumed an intermittent course before becoming normal on the thirty-fifth day of disease. Enlargement of the glands of the neck were first noticed on the nineteenth day of disease and a few days later the axillary and inguinal glands became enlarged. No enlargement of the spleen, however, was detected. In both the mother and daughter convalescence was rather slow, and it was not until May 21st that they were discharged on the fifty-eighth and sixty-first day of disease respectively. The enlargement of the glands in the axilla and groin had then subsided, but the cervical glands were still enlarged in both patients.

The following reports on the mother's blood were made by Dr. McCartney :—

"April 5th : Weil-Felix reaction negative. Widal reaction negative to *B. typhosus*, *B. paratyphosus* A, and *B. paratyphosus* B. Wassermann reaction negative. Blood cultures showed an organism with the characteristic features of *Streptococcus fæcalis*, which was regarded merely as a contaminant.

Differential count, April 17th : Polymorphs 33 per cent., large lymphocytes 62 per cent., small lymphocytes 2 per cent., large mononuclears 3 per cent. Eosinophils and mast cells nil. The polymorphs show signs of immaturity, in many of them the nucleus is not lobed but merely horse-shoe shaped. The red cells vary considerably in size, but there is no poikilocytosis. No nucleated red cells were seen. A few of the red cells showed punctate basophilia. No parasites were seen. The total cell count is not known, but the blood has the appearance of acute glandular fever (infective mononucleosis)."

The total leucocyte count was subsequently found by Dr. Laurent to be 7640 per c.mm. A second examination of the blood made on May 8th differed from the first in that the Wassermann reaction was positive, while the differential count (polymorphs 19 per cent., eosinophils 5 per cent., small lymphocytes 6 per cent., large lymphocytes 69 per cent., large mononuclears 1 per cent.) was remarkable for the high percentage of eosinophil cells.

COMMENT.

The resemblance to typhus in the two cases under consideration were the sudden onset, the high fever, the bronchitis, deafness, retention of urine in the younger patient, and the positive Wassermann reaction. On the other hand, the points against such a diagnosis before the appearance of the glandular enlargement were the indefinite character of the eruption, the negative diazo reaction, and the absence of any known source of infection.

Although there is no characteristic eruption in glandular fever, several writers such as Glanzmann,[3] Tidy,[4] and Evans and Robb [5] have recently drawn attention to the occurrence of rashes resembling scarlet fever, measles, rubella, or the rose spots of enteric fever, but we have not found any previous mention of an eruption in glandular fever resembling that of typhus.

The immunity from typhus which London has enjoyed for many years and the absence of any known exposure to infection seemed to be an even more important argument against the diagnosis of typhus. As J. D. R. had occasion to remark at the aforesaid discussion on tropical typhus[1] during the 30 years in which he had been in fever practice there had been only 71 cases of typhus, of which he had seen about a dozen, admitted to the Metropolitan Asylums Board hospitals, and the last case in which the diagnosis had been confirmed was in 1918.

After the woman's admission to hospital, the father and the only other child, a girl aged 9, was examined by M. R. in order if possible to trace the course of infection. Though he was in a bad state of health, having recently undergone malaria treatment for general paralysis, the father was not suffering from any acute illness, and examination of his blood by Dr. F. H. Teale gave the following results :—

Wassermann reaction completely positive. Weil-Felix reaction negative. Widal reaction : agglutination with *B. paratyphosus* B completely positive in dilutions 1 : 25, 1 : 50, 1 : 125, 1 : 250, 1 : 500. Culture : no growth of organisms. No organisms of the typhoid or paratyphoid group were isolated from the stools.

The child appeared to be in good health and gave negative Widal, Wassermann, and Weil-Felix reactions, but on April 12th we learnt that the younger patient's cousin had been admitted to St. Bartholomew's Hospital with symptoms resembling those of the supposed typhus cases, and on a visit to this hospital we found that she had been diagnosed as suffering from glandular fever. The positive Wassermann reaction which at first seemed to favour the diagnosis of typhus was afterwards thought to be connected with the paternal syphilis, but on inquiry it was found that the father had contracted his infection after the daughter's birth, and we have since been informed that several cases of glandular fever in which no other evidence of syphilis was obtained gave a positive Wassermann reaction. The late development of any obvious glandular enlargement is by no means unusual in glandular fever, as Glanzmann and Evans and Robb have recently shown, and as one of us (J. D. R.) had an opportunity of observing through the kindness of Dr. Cecil Wall in several cases at the London Hospital, as well as in another case sent to the Western Hospital as scarlet fever, in which the adenitis did not appear till the thirteenth day of disease.

RETROBULBAR NEURITIS AND DISSEMINATED SCLEROSIS.

By C. P. Symonds, M.D.Oxf., F.R.C.P. Lond.,

PHYSICIAN IN CHARGE OF DEPARTMENT FOR NERVOUS DISEASES, GUY'S HOSPITAL ; ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN-SQUARE.

It is well recognised, both by ophthalmologists and neurologists, that acute retrobulbar neuritis is a common symptom of disseminated sclerosis and may occur as the first manifestation of this disease. The literature upon the subject has been recently reviewed by Brain,[1] who concludes that "every case of retrobulbar neuritis for which no other cause can be found should be regarded as a possible case of disseminated sclerosis," and that "it must be borne in mind that the absence of further symptoms for many years does not exclude the possibility of the ultimate development of disseminated sclerosis."

The question of frequency of this symptom in disseminated sclerosis is one that has interested me for some time, and in view of the relative paucity of papers dealing particularly with this point it has seemed to me worth recording some personal observations. These are taken from a series of cases seen in private practice under conditions which permitted a careful examination of the history obtained from patient and relatives with particular

[1] Brain, W. Russell : Quart. Jour. Med., 1930, No. 91. p. 343.

reference to visual disturbance. This is a matter of some importance, for a story of retrobulbar neuritis in the past, often attributed at the time to some plausible infective or toxic cause and ending in recovery, is not likely to be connected in the patient's mind with a subsequent weakness or numbness of the limbs. Moreover, the memory of many patients with disseminated sclerosis is defective by reason of their disease. Unless, therefore, the point is carefully inquired for in every case the incidence is likely to appear lower than it really is.

In a series of 139 cases of disseminated sclerosis in which the clinical diagnosis appeared certain, a history of an attack of retrobulbar neuritis was obtained in 39, or 28 per cent.

Of equal interest is the proportion of cases in which retrobulbar neuritis is the *first* symptom of the disease. This has been estimated by American and French authorities, quoted by Brain, as something under 10 per cent. In the present series the onset of retrobulbar neuritis preceded all other symptoms in 20 cases and appeared together with other symptoms at the onset in another six. In two-thirds, therefore, of the cases in which retrobulbar neuritis occurred, it marked the onset of the illness, and of the total number of 139 cases under review retrobulbar neuritis occurring alone was the first symptom in roughly 15 per cent.

A further question of interest in relation to the ætiology of those cases of retrobulbar neuritis usually regarded by the ophthalmologist as of uncertain or obscure origin is the interval, when retrobulbar neuritis is the first symptom of disseminated sclerosis, before other signs of the disease appear. Of the 20 cases in this series, further symptoms developed in under 2 years from the onset of the retrobulbar neuritis in ten cases, in over 2 years but under 5 years in five cases, and in the other five cases the latent interval was over 5 years.

The following summaries from the notes of three of these cases illustrate the length to which this latent interval may extend :—

1. Mrs. A, aged 42, seen Jan. 1st, 1930. Three years ago partially lost power in the legs. At the same time use went out of left hand. Improved, but recently walking worse. Diplopia during past month. Admitted on questioning that in 1913 she quite suddenly lost the sight of one eye. This recovered in about three weeks. Then the other eye went blind, and recovered in a similar period. On examination pallor of both discs, nystagmus, intention tremor left upper limb, spastic weakness of lower limbs, with extensor plantar responses.

2. Miss B, aged 24, seen June 12th, 1929. One month ago an attack of vomiting and vertigo. During past few days numbness in right hand. Admitted on questioning an attack ten years previously at the age of 14 of dimness of vision in both eyes associated with severe headache. Was seen by an ophthalmic surgeon who diagnosed retrobulbar neuritis. On examination pallor both discs, nystagmus, loss of postural sense fingers of right hand, absent abdominal reflexes, right plantar response extensor.

3. Mr. C, aged 60, seen August 24th, 1927. Two years ago noticed difficulty in walking which has progressed. Eighteen years ago suddenly lost vision in right eye. Diagnosed retrobulbar neuritis. Saw many ophthalmic consultants with various opinions as to cause ; sight improved. Five years ago left eye similarly affected and improved. On examination primary optic atrophy with bilateral central scotoma, nystagmus, slight spastic weakness of left upper limb, and marked spasticity and weakness of both lower limbs, with extensor plantar responses. The Wassermann reaction in blood had been tested many times, and was found negative on all occasions.

It follows that in a case of retrobulbar neuritis of obscure origin disseminated sclerosis remains a possible cause, even if no further signs of this disease have developed after a period of 10 or 15 years.

MEDICAL SOCIETIES

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

AT a meeting of this Society on June 19th, with Dr. G. CARMICHAEL LOW, the President, in the chair, a paper on the

Pathology and Treatment of Sprue

was read by Dr. N. HAMILTON FAIRLEY. Having had the doubtful advantage of suffering from sprue for two years, he said, he had been able to assess the value of various forms of treatment on his own *corpus vile*. As regards causation, there was only one recent piece of positive evidence—namely, Mackie's isolation of a pleomorphic organism resembling *Bacillus mallei*—and none of the ætiological theories had in any way modified the treatment. Pathologically, the disease was essentially an atrophic degeneration of the digestive tract, with megaloblastic inflammation of the bone-marrow. The intestinal lesions, which were primarily inflammatory and secondarily atrophic, had a notoriously patchy distribution and, in the later stages, implicated the whole tract. At times, however, the main brunt of the attack might fall on the ileum, the jejunum, the stomach, or the tongue. Dr. Fairley suggested that derangement of the ileum specially underlay defective absorption of fat, vitamin D, and calcium, and that jejunal involvement, leading to an inevitable decrease in the secretion of succus entericus, prevented normal splitting of cane sugar, lactose, and maltose. Abnormal fermentation of the resulting disaccharide residue was largely responsible for abdominal distension and the acid, gaseous stools so characteristic of sprue, while their increased fat content contributed largely to their bulkiness. Involvement of the stomach was indicated by the frequency of defective acid secretion, and, as in pernicious anæmia, deranged gastric secretion probably underlay the megaloblastic hyperplasia of the marrow and the megalocytic anæmia so characteristic of sprue. No essential relationship, however, exists between megalocytic anæmia and achylia gastrica, for several of the present series showed anæmia of this type associated with a free secretion of HCl. Dr. Fairley thought that the aplasia of the megaloblastic marrow might result from malnutrition, being analogous to the corresponding changes produced in the normal megaloblastic marrow of pigeons undergoing starvation. It had been shown that total as well as the ionic serum calcium was often reduced in sprue, and that this reduction was unaccompanied by an increase in the inorganic phosphorus. Marked lowering of the serum cholesterol was a characteristic finding in the severer cases.

TREATMENT.

The essential principles in the treatment of sprue might be summarised as follows : (1) alimentary rest ; (2) restoration of the blood to a normal condition ; (3) reinforcing demonstrable deficiencies such as lowered blood calcium and defective HCl secretion.

The most rational method of obtaining alimentary rest was by administration of a high protein, low fat, low carbohydrate, and adequate vitamin diet. The effects of a high protein diet were very obvious clinically since the stools showed a fall in their fat content, became neutral or alkaline in reaction, and rapidly decreased in bulk and number, while abdominal distension and intestinal flatulence disappeared. During the first two or three weeks weight may be lost or little gained, but once the bowel has been adequately rested and the anæmia rectified, higher caloric diets were well tolerated. Where patients were specially emaciated or the weight-curve fails to show the customary rise, insulin in doses of 6 to 12 units daily might be employed with striking benefit.

In all cases of megalocytic anæmia Dr. Fairley had given liver extract in full dosage (=1¼ lb. daily). Steady improvement in the red cell counts and percentage of hæmoglobin had followed, and generally a reticulocyte response whose intensity was inversely proportional to the gravity of the anæmia. Anæmias not frankly megalocytic in type had also improved under this régime, but reticulocyte response was absent. It has not yet been ascertained to what extent purely dietetic measures were responsible. Where the total serum calcium was below 9·0 mg. per 100 c.cm., calcium lactate or calcium and sodium lactate were administered, and in special cases irradiated ergosterol (vitamin D) was also given. In addition, a low fat diet was always instituted. Restoration to a normal blood calcium level invariably followed treatment along these lines, and generally paralleled improvement in alimentation. HCl was supplied in adequate dosage to all cases where its secretion was proved defective.

After prolonged experience of tropical sprue, Dr. Fairley is convinced that clinical observation should always be reinforced by biochemical and hæmatological data whenever possible, and also that in a disease so notoriously liable to relapse every patient should from time to time report for medical examination. Nor should treatment cease with discharge from hospital. Over-fatigue, extremes of temperature, and cold and chill must be avoided; and for many months, or even years, the diet may need careful supervision, especially in regard to carbohydrate excess. In cases of achylia gastrica and achlorhydria continued administration of HCl and a maintenance daily dose of liver extract equal to ¼ lb. of the fresh organ is advised until such time as normal gastric secretion be restored.

DISCUSSION.

Colonel F. P. MACKIE agreed with Dr. Fairley in his main points. He had been associated with him in researches on sprue for so many years that much of the work that led up to this paper had been done conjointly.

Dr. P. MANSON-BAHR, as a result of a study of 200 cases of sprue treated during a survey of seven years' work at the Hospital for Tropical Diseases, was able to show graphs which illustrated from strictly clinical observation the bases of many of the principles Dr. Fairley had laid down. The increase in body-weight corresponded in a remarkable way with the decrease in the amount of stool passed, and the curve in improved nutrition runs parallel with the improvement in the blood as graphed in results of red cell counts and hæmoglobin values. His results, which were being published in the near future, indicated that sprue was a specific inflammation of the gastro-intestine, with a definite incubation period, but that the virus was capable of lying latent in the human body for a very considerable period—a period of sometimes 8–25 years. His indications for treatment were the same as Dr. Fairley's, and were based upon the principle of complete alimentary rest until such time as absorption through the small intestine had increased combined with renewed secretion of the succus entericus. His treatment consisted of partly milk and partly high protein dietary, with the exclusion, as far as possible, of a high fat and carbohydrate content. His experience, looking back over ten years, had been fairly satisfactory.

Dr. G. M. HARSTON referred to the favourable effects of heliotherapy in sprue which he had seen in Hong-Kong, and which corroborated the experience of Dr. Manson-Bahr and Dr. Fairley at the Hospital for Tropical Diseases.

Dr. G. W. GOODHART suggested that there was a great difference between the nutrition of the skin in sprue and in pernicious anænia. Another essential difference was the almost immediate and striking increase in body-weight in pernicious anæmia on a protein dietary, whereas a similar rapid increase did not occur in sprue on a high protein non-residue diet.

The PRESIDENT, on the strength of 30 years' experience of treating sprue, made critical comments on the lasting value of the various forms of treatment advocated during that period.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OTOLOGY.

THE summer meeting of this Section was held at Nottingham on June 27th and 28th, with Mr. W. M. MOLLISON, the President, in the chair.

A paper on disturbances of hearing in

The Adenoid Child

was read by Prof. GUIDO GUIDA, who said that at the first sign of deafness in a child specialist advice should be secured, for at this early stage it would usually be possible to avoid lasting disability. In various provinces of Italy a Government inquiry showed that from 10 to 50 per cent. of the children with adenoids had defective hearing. There were also cases in which adenoids were associated with a subnormal mentality. The Italian Government had instructed provincial authorities to organise special agencies against "adenoidism," and these were supposed to coöperate with existing hospitals and clinics. Cases detected in schools were sent to the proper place. Prophylaxis was first carried out for some days in the form of inhalations of calcium or iodine. It was very neessary that frequent examinations of the patient's hearing should also be made.

The PRESIDENT said the profession in this country did not claim to have yet discovered the reason why children had enlarged tonsils and adenoids. He would like to know more about the effects of the prophylactic use of calcium and iodine.

Mr. SYDNEY SCOTT was glad that the Italian Government insisted that these operations should be done only by specialists. Too often in the less populous parts of this country medical men with little or no special qualification for the work had been appointed to clinics.

Mr. H. BELL TAWSE alluded to the investigation made during the last five or six years by a committee of the Board of Education. So far most of the inquiry had concerned children of school age, and had yielded little positive result. It was clearly necessary to go back to the years before school age. In the next few years that committee would issue a further report. An 18 months' trial of bicarbonate of soda for a time before the operation—grs. 10—had resulted in much less post-operative bleeding than formerly.

Mr. L. GRAHAM BROWN said that before the war children were usually brought for operation at 14 to 16 years of age, whereas now the majority brought were between the ages of 4 and 6. This, he thought, showed that the authorities were becoming increasingly appreciative of the close relation between adenoids and deafness. It was very important nationally that adenoids should be recognised and treated early. However young the child, if symptoms pointed to the need, the operation should be carried out. He had noticed that many children sent back for a repetition of the adenoid operation had nothing more than nasal catarrh; medical officers hastily assumed that the condition was adenoids without adequate examination. Some of these children had maxillary sinus suppuration.

Mr. HAMBLEN THOMAS said the London County Council were endeavouring to ascertain the cause of adenoids. Attempts had been made to continue the examination of the children over a period of five years, but towards the end of that time so many failed to appear that convincing statistics could not be compiled. The dietetic factor was important. Children should be examined before school age, for often the damage had been done by the fifth year.

Dr. A. LOWNDES YATES pointed out that it was not until the fifth year that the permanent teeth passed into their adult position, the antrum was enlarged, the ethmoids began to increase, and the middle turbinal came into the nasal airway. Adenoids should not be removed at a very early age, for they had a definite function in removing dust and micro-organisms before the more adult mechanism was fully established. He had noted that when children were exposed to a highly infective environment—as when the mother had much pyorrhœa or ozæna—they formed adenoids early. But if the mother's infective condition was cleared up, the child's adenoids also got well. Excess of lymphoid tissue in these children thus seemed to be a result of sepsis, doubtless coupled with wrong food and other errors. Investigation along these lines would probably be fruitful.

Mr. W. S. THACKER NEVILLE remarked on the lack of provision in this country for the mass examination of school-children for deafness.

Mr. HUGH E. JONES said that many children were sent by school authorities for operation for tonsils and adenoids who did not need it. In most cases the reason was that the children were not examined by experts, nor even by medical people, but merely by a mistress or assistant master. Examination of school-children should be carried out by competent people. He advocated for use on children a much smaller guillotine than was usually employed. Children of 1½ to 2 years should not be subjected to the adenoid operation unless there was obvious interference with breathing.

Mr. T. B. LAYTON agreed with Dr. Lowndes Yates in looking upon adenoid tissue as a physiological structure to be conserved in early life. Adenoids, he thought, were pathological only when they obstructed either the posterior nares or the Eustachian tube, or both. He was carrying out two kinds of operation, according to whether the indication was nasal or aural. If the latter, he removed the lymphoid tissue round the Eustachian tube, leaving the tissue in the mid-line. The child living under bad conditions needed all its lymphoid tissue to combat infection; hence those living in dense slums should not be subjected to the operation. He inquired of parents how many rooms they occupied, and if overcrowding was indicated he did not operate; and so far he had seen no reason to regret that policy.

Mr. HAROLD KISCH said that he had been for a time in contact with a European colony in India, living at an altitude of 5000 feet, and though the children were well looked after, and had enough good food with milk, they had enormous tonsils and adenoids. He operated on all of them. He was sure tonsils were sometimes a definite focus of infection; on at least two occasions he had removed a pad of adenoids with an abscess inside, and he had seen glandular masses elsewhere disappear after adenoids had been removed. When adenoid operations had been done for deafness, the children should be kept under observation, and inflation should be done.

Mr. C. A. RIDOUT said that in many cases of supposed sinus infection after recurrent adenoids the condition was nothing more than nasal sepsis. That was another reason why these operations should be done by competent laryngologists, otherwise many cases of sinusitis would be missed. In some cases the trouble would disappear spontaneously with the development of the sinuses.

Mr. F. W. WATKYN-THOMAS said that in a number of cases of so-called recurrent adenoids there could be seen a felted mass of mucosa extending from one pillar to the other, the whole condition being obviously associated with nasal sepsis.

Prof. GUIDA, in reply, said it was the custom in Italy to test the hearing of school-children, and sometimes before operation they were sent to have inhalations of 5 per cent. chlorine and chloride of calcium. Iodine was also used in the form of iodine-charged waters, or many children seated in a room could inhale iodine-charged vapour from a kettle. Ten per cent. were cured of their deafness by the adenoid operation. Children were not operated upon in Italy younger than 3. The hearing tests were carried out separately on each child, not en masse.

Dr. A. LOWNDES YATES read a paper on

Repair in the Middle Ear.

Five years ago, he said, when he was interested in the repair of nasal and of aural epithelia he found that in certain cases although repair of the epithelium took place apparently the hearing did not become normal. He therefore carried out experiments to ascertain the relation between the healing process and the restoration of the middle-ear function. Working on a model of the middle ear, in which a microphone connected with a loud speaker was fitted in place of the cochlea, he found that in the artificial middle ear there were three primary positions of the ossicles: (1) a position of rest, in which only penetrating or loud sounds were heard; (2) a position of listening, in which the ossicles lay in a position in which there was maximal hearing of all notes; (3) a position in which the membrane was indrawn, similar to that at the summit of a wave of sound when it fell on the membrane. This last position he characterised as that of "having heard." Thus deafness might result either from maintaining the position of rest or that of "having heard."

If the membrane was indrawn it was the custom to inflate the ear, but in most cases this was not good practice, because the infective products which blocked the tube and caused the vacuum might be blown into the cavity of the middle ear and there cause inflammation. A better plan was to aspirate the mucus from the interior of the Eustachian tube by the catheter designed by Weber and Liel. Cerumen was secreted in a very fluid form and ran over the tympanic membrane, thus oiling it and preventing the evaporation which perhaps occurred from the mucus present in the middle ear. It seemed clear that evaporation could occur through the tympanic membrane, and in mild conditions of inflammation repair might thus be hindered. In subacute otitis media the membrane was sometimes pushed out by mucus lying between it and the inner tympanic wall. This mucus was removed at intervals by the action of the cilia. In these cases there was pain and, later, a partial deafness which increased in degree, and the alterations in hearing were similar to those by which otosclerosis was diagnosed.

If the view was accepted that listening was, in part, the result of the contraction of the tensor tympani which brought the cog processes of the malleus and the incus into contact, then repair within the middle ear might be complete, but leave the structures in a position which made listening difficult. In many of the cases which showed a high degree of auditory fatigue there was evidence of a lesion of the perceptive mechanism. In some in which such was not the case it was found that the patients had no power of resting their ears, and the mechanism of the middle ear was retained in the position of listening.

Dr. Yates described his experiments on the character and action of mucus, and said that repair within the middle ear seemed to depend on the interplay of two mechanisms: that concerned with the removal of the mucus by the cilated epithelium, and that concerned with destruction of the agents causing infection. When mucus contained leucocytes and such organisms as the *Staphylococcus aureus*, desquamation was not great, and the ciliated epithelium began to act again quickly after the inflammation subsided. When, however, the cells visible in the mucus represented desquamated epithelium, repair was much slower. The proteolytic ferments elaborated by the micro-organisms were the most important element in the prevention of repair in the leucocytic type of inflammation; it was, indeed, these ferments which caused the perforation of the membrane.

Otosclerosis was a condition of the labyrinthine capsule, and so was a state which could not be recognised until the ear was examined post mortem. Otology would be much helped if the term "otosclerosis" were dropped and research were centred round the desquamative types of inflammation, which produced symptoms indistinguishable from those said to be present as a result of the lesions of the labyrinthine capsule. His treatment of these cases had been successful only in the early stages; it was to carry out repeated aspiration of the Eustachian tube, combined, where necessary, with myringotomy. If the membrane was pushed out in minor states of inflammation, a type of deafness resulted which had been described as an inability to listen. If this was present during the active stage of inflammation, myringotomy would relieve the tension, and the need for this must be diagnosed by the results of the hearing tests. In every state of inflammation of the middle ear the repair might be prevented by conditions which affect the general health.

The speaker submitted the following conclusions:—

(1) When repair occurs within the middle ear it does so because of the activity of the bactericidal action of the mucus and of the cilia which move the mucus on. The state of repair of this region can be assessed to some extent by the discharges which lie within the tube or which escape through the perforation in the tympanic membrane. It is important to recognise the two main types of inflammation in the ear—the eucocytic and the serous—and to try to treat each in the appropriate way.

(2) Most of the lesions causing deafness arise as a result of inflammation in the middle ear; and the two primary positions in which the normal ear hear with diminished acuity are that of "having heard" and the position of "rest." The two common forms of deafness may be due to the auditory mechanism becoming fixed in these positions, while fixation may occur in the position of listening which make it impossible to rest the ear.

A discussion followed.

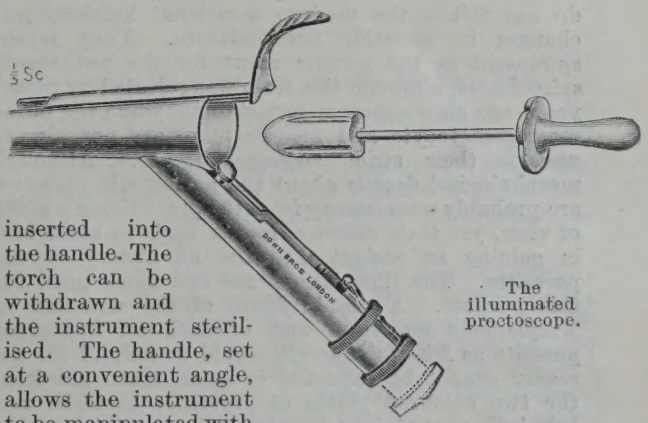
OTHER COMMUNICATIONS.

The meeting then considered the preliminary report of the committee appointed by the Section to inquire into hearing tests.—Dr. H. MUIR EVANS read a paper, supported by numerous slides and some specimens, on the Swim Bladders of Fishes and Weberian Ossicles, and Dr. YATES gave a demonstration of sound records, explaining the principles of the talkie machine.—On Saturday a series of clinical cases were shown, and the remaining items consisted largely of demonstrations, among them one on the galvanic method of testing the auditory apparatus.—Mr. G. WILKINSON spoke on some mechanical problems in the construction of cochlear models.

NEW INVENTIONS

AN ILLUMINATED PROCTOSCOPE.

THE proctoscope here illustrated has been designed specially to meet the requirements in the modern treatment of hæmorrhoids by injections. The illumination is obtained by a standard pocket torch inserted into the handle. The torch can be withdrawn and the instrument sterilised. The handle, set at a convenient angle, allows the instrument to be manipulated with ease. The conical shape gives ample room for injections to be made whilst the mucous membrane remains under observation. As a rule injections are made with the slide in position. The instrument can then be rotated without reinserting the obturator. The site of the injection can be accurately determined by withdrawing the lateral slide. The instrument is equally useful in routine rectal examinations and in minor rectal surgery. For use in operative work a similar instrument on a slightly larger scale is more useful.



The illuminated proctoscope.

This proctoscope has been made by Messrs. Down Bros., Ltd., St. Thomas's-street, London, S.E.

PETER G. MCEVEDY, F.R.C.S. Eng.

REVIEWS AND NOTICES OF BOOKS

Tropical Medicine.

By Sir LEONARD ROGERS, C.I.E., M.D., F.R.S., Major-General, I.M.S. (Ret.), Medical Adviser to the India Office; and JOHN W. D. MEGAW, C.I.E., M.B., Director-General, I.M.S. Churchill's Empire Series. London: J. and A. Churchill. 1930. Pp. 536. 14*s*.

THE joint authors of this book have contributed in great measure to the advancement of tropical medicine. Many years' experience in clinical and pathological teaching work in India has convinced them of the need for a small book which describes such simple microscopical work as the practitioner in the tropics can carry out himself. The existing works on tropical medicine, they consider, meet the detailed demands of readers anxious to qualify for a diploma rather than those of the practising doctor.

The conception and also the arrangement of the subject matter is novel. Tropical diseases are classified into ten sections, of which the more important are headed: febrile diseases caused by protozoa, febrile diseases caused by spirochætes, febrile diseases of uncertain origin, the typhus fever group, bacterial febrile diseases, bowel diseases with symptoms of diarrhœa and dysentery, diseases associated with diet and those caused by heat and light. This clinical classification is straightforward and easy to follow. Much space is devoted to the history of tropical medicine, and here the teaching differs in some details from that usually given. Some chapters, as Chapter IX. on the typhus group and Chapter XXIV. on climate as a disease factor, deserve especial praise. In the matter of terminology we note that the authors do not follow the modern somewhat kaleidoscopic changes in scientific nomenclature. They retain *spironema* as the generic name for the pathogenic spirochætes, although this term was rejected by Styles years ago on account of fore-stalling, while the terms macrogametocyte and macrogamete are not always used in their strict zoological sense. Although morphological details about the pathogenic parasites are probably unnecessary from the practitioner's point of view, yet their absence leaves little to assist him in gaining an insight into the life-history of the parasites. The illustrations are not much good for this purpose. A simple figure of the structure of *Ancylostoma duodenale* and of such an important parasite as *Filaria bancrofti* would be helpful, for the reader cannot be expected to glean much aid from the two coloured plates of protozoa, bacteria, and helminth eggs stained in various ways, which are so reduced in size as to become difficult to decipher. The same criticism may be levelled at the black and white figures giving in brief the story of a disease. The sections on treatment are satisfactory on the whole, though some of the statements are rather too dogmatic. The authors show but little enthusiasm for certain drugs which have received wide support. For example, plasmoquine in malaria, and Bayer 205 in trypanosomiasis, and yatren in amœbiasis. There is surely no justification for stating that *Filaria bancrofti* has a "diurnal periodicity" (p. 385), or that the Planorbis snail is furnished with an operculum (p. 413). The book is in the main accurate and is full of good material.

The Adolescent: His Conflicts and Escapes.

By SIDNEY I. SCHWAB, M.D., Professor of Neurology; and BORDEN S. VEEDER, M.D., Professor of Physical Pediatrics, Washington University. London: D. Appleton and Co. Pp. 365. 10*s*. 6*d*.

THE sudden burden that is placed upon the adolescent at puberty has both physical and its mental components. The fructifying of the sexual life has its repercussion upon both body and mind, and it is the ability of the human being to bridge this perilous gap that marks future failure or success in life. Although modern psychology rightly stresses the first five years of life as formative of character, the period of puberty is certainly second in importance. The authors have introduced their subject very naturally by reference to the physical growth and development of the adolescent, but they realise that the psychological mechanisms involved in the process of maturing and of adjusting social life are of paramount importance. They therefore analyse in great detail every aspect in the life of young persons of both sexes at this turning point. They tend to take an environmental view of the conflicts and adjustments, normal and abnormal, which characterise the life of the adolescent. Sex, too, is rather cleverly treated as an environmental factor and not as an internal urge alone. This is a very important point of view, because there is no doubt that the sexuality of young persons is largely coloured by the milieu in which they find themselves. But, on the other hand, while the Freudian theories are discussed, the authors do not give Freud all the credit for having explained the deep significance of some of the conflicts of puberty which can only be superficially understood in terms of immediate problems. Any student of dementia præcox knows that the stress which is alleged to have precipitated the pathological introversion is usually quite inadequate to explain the depths to which the cleavage in the mind usually goes. The result is that in the authors' discussion of personality problems their treatment of this nuclear problem in psychopathology appears too superficial. For those, however, who require a guide to the understanding of the immediate problems of adolescence this book can be cordially recommended.

Roentgenographic Technique.

By DARMON ARTELLE RHINEHART, A.M., M.D., Professor of Roentgenology and Applied Anatomy, School of Medicine, University of Arkansas; Roentgenologist to St. Vincent's Infirmary. London: Henry Kimpton. 1930. With 159 illustrations. Pp. 388. 28*s*.

BELIEVING that all books on radiographic technique "are either obsolete or incomplete in some particular," Prof. Rhinehart set to work to write a new manual for physicians, students, and technicians, which should be free from such defects. He has certainly produced a fine and original work. He criticises the usual presentation of radiographic technique for making no provision for differences in the apparatus or equipment at disposal; moreover, it is usually based on a hypothetical patient of certain dimensions. By introducing a series of experiments to determine the operating peculiarities of each machine, by pro-

viding a simple experimental method of gauging the effective output of each equipment, and by basing exposures on the thickness and radiographic density of the parts of the body, he claims to produce a standardising technique, irrespective of the diverse conditions that are met with. In the experiments described, the reader is instructed how to build up charts and graphs suited to his own conditions of work—e.g., a thickness-voltage chart, and considerable use is made of teeth embedded in paraffin blocks to determine the necessary voltage to produce a radiogram of satisfactory quality through various thicknesses, corresponding, of course, to different parts of the body. Everything is worked out so that standardisation can be obtained with such apparatus as is available.

The first half of the book deals with the physical and technical side of radiology, leads up through experiments to "a basic roentgenographic technique," and includes very useful miscellaneous instruction. The second half gives the applied technique for different parts of the body. The final chapters on the urinary tract and on localisation are hardly up to the standard of the rest of the book. When giving instructions on localisation the author might have quoted more fully from the excellent American Army X Ray Manual to which he refers. In the section on the gall-bladder, Prof. Rhinehart strongly advocates the oral administration of the dye. He says: "We have examined several hundred patients by means of cholecystography. A short and stormy experience with the intravenous method prompted its complete abandonment in favor of the oral administration." It is permissible to wonder what tragic story lies behind this statement, for in most centres the oral method had an uphill fight to obtain recognition, and the advocates of the intravenous method held the field for years, in spite of the obvious disadvantages of a minor operation.

The chief value of the book is that it records the practical personal experience and judgment of one who has made himself master of his subject. It will surely be of great value to all students and practitioners of radiology.

Lehrbuch der klinischen Untersuchungsmethoden für Studierende und praktische Ärzte.

Seventh edition. Von Prof. H. SAHLI. Vol. II. First part. Leipzig and Vienna: Franz Deuticke. 1930. Pp. 368. M.22.

THE present edition of Prof. Sahli's well-known handbook has numerous additions. The new methods introduced are confined to those which have a real value in clinical medicine. The multiplication of biochemical and other methods of investigation in recent years has been excessive, and we welcome the stand that Prof. Sahli has taken in discountenancing technical procedures that inflict discomfort or even danger to the patient out of all proportion to the value of the results produced. The abundance of alternative methods may so encumber medical diagnosis that essential points may be overlooked. The choice from such alternatives must be a matter of scientific knowledge and not of intuition, which, as Prof. Sahli remarks, is based upon hard work and observation, and is not an "art" inherent in some and lacking in others. Of those methods which he regards as really helpful and advantageous to a patient he gives a full and practical account. This volume deals with methods of examination of the urine, sputum, and blood, and provides detailed descriptions of technique as well as critical considerations of the results obtained.

New matter includes tests of renal and liver function, vital staining of the red cells, and discussions on the leukæmias and on gout. Throughout the work there is an emphasis upon fundamentals for which all Prof. Sahli's work is famous.

Minor Surgery.

Second edition. By ARTHUR E. HERTZLER, M.D., Chief Surgeon, Halstead Hospital; and VICTOR E. CHESKY, M.D., Chief Resident Surgeon to the Hospital. London: Henry Kimpton. 1930. Pp. 602. 42*s*.

THE avowed object of this book is to help what is termed the "dispensary student" to understand what he sees in the out-patient clinic. With this object in view discussions on pathology are omitted, and treatment is mostly referred to only in general terms, detailed technique being given where the authors have a particular method of their own. In so far as the book is magnificently illustrated, while typical lesions are clearly reproduced, it admirably fulfils its object. The authors' clinical material must be extensive and it has been utilised to fullest advantage. We have all sat as students in out-patient departments waiting to see and examine "lumps," and everything that could come into that category is here illustrated and described. If the student working in the out-patient department wants to read about a lesion in all its aspects he will be disappointed in this book, where he will find merely a brief account of the condition as it is seen clinically, and a scanty outline of its treatment and prognosis. But if he seeks description and illustration of the early picture of any disease of which he has seen an advanced stage he may find here exactly what he wants.

Slit-lamp Microscopy of the Living Eye.

Second edition. By Dr. F. ED. KOBY (Basle). Translated by CHARLES GOULDEN, O.B.E., F.R.C.S., Surgeon to the Royal Ophthalmic (Moorfields) Hospital; and CLARA LOMAS HARRIS, M.B. London: J. and A. Churchill. 1930. With 104 illustrations. Pp. 360. 15*s*.

ON its introduction the slit-lamp was regarded by many ophthalmic surgeons as little better than a toy, as far as its practical applications are concerned. Further experience tends to refute this opinion, and it must now be admitted that ability to use and interpret the slit-lamp is essential to the complete training of the ophthalmic surgeon of the future. This means that the student must devote some time to acquiring familiarity with the technique, and for this he will need an efficient teacher and a good book. In the periodical courses of instruction that are given at Moorfields Hospital this translation of Prof. Koby's book is used as a text-book. Koby's expressions are sometimes unnecessarily mathematical. For example, the convenient name given by Harrison Butler to the portion of the cornea illuminated by the narrow slit is "corneal prism," though it is admittedly not a prism in the ordinary sense. Koby calls it a "parallelopiped." It is, of course, only the anterior parts of the globe that are accessible to examination by the corneal microscope. With the

aid of the illumination provided by the slit-lamp it is now possible to detect minutiæ in either the normal or the pathological structure of the cornea, anterior chamber, iris, lens, and anterior part of the vitreous. The chief practical applications, that have so far been made, relate to corneal opacities, their depth and nature, the structure of the lens and the various varieties of cataract, changes in the structure of the iris, and the detection of particles in the aqueous humour, and of slight degrees of precipitation in Descemet's membrane. The most definite result to date of slit-lamp illumination is the discovery of various zones of discontinuity in the substance of the lens which have led to an entirely new nomenclature describing its structure, these being now distinguished from within outwards as embryonic nucleus, fœtal nucleus, adult nucleus, and cortex.

Diseases of the Blood.

By PAUL W. CLOUGH, M.D., Associate in Clinical Medicine, Johns Hopkins University. London: A. and C. Black, Ltd. 1930. Pp. 310. 6s.

In the exposition of any given subject there are those whose aim appears to be to render the simple as complex as possible; there are others who have the gift of rendering the relatively complex simple. The study of hæmatology has always attracted an unfortunately large proportion of the former class. Dr. Clough has the gift of clear exposition and knows how to avoid unessentials; what is more, he has the rare power of mastering and of applying general principles. This little work of only just over 300 pages contains more useful and well-arranged material than many more pretentious volumes of three times its size and six times its cost. On his first page the author takes care to point out that there is no such thing as a "disease of the blood;" he then sets forth concisely all that is known about the conditions usually considered under that head. Throughout the information is up to date and accurate. The book is not overloaded with illustrations, but such plates as are provided are excellent. It is refreshing to read a book on the blood in which it is neither assumed nor stated that 5,000,000 per c.mm. constitutes a divinely ordained normal for the red cells; in which it is made clear that there is no consensus of opinion as to what constitutes 100 per cent. of hæmoglobin; that the volume index is of even greater importance than the colour-index in the diagnosis of pernicious anæmia; and that nothing is to be gained by attempting to differentiate beween "large" and "small" lymphocytes or between monocytes and "transitional" cells. This will be a good book for students when examiners are educated up to its standard.

La rachianesthésie: sa valeur et sa place actuelle dans la pratique.

By E. FORQUE and A. BASSET. Paris: Masson et Cie. 1930. Pp. 222. Fr.30.

Prof. Forque and Prof. Basset have produced a comprehensive and judicial account of spinal analgesia. Unfortunately, the most recent developments in this line, spinocain "controllable anæsthesia" and percain, are not mentioned; probably neither of them had been made known while the book was being written. A large part of the work is devoted to physiological considerations, for the authors maintain that it is only on our full knowledge and understanding of the physiology of the cerebro-spinal fluid and of the spinal nerves that proper practice can be founded. They attribute the wide variations in technique to the fact that there is no clearly laid down and generally accepted account of the physiological problems involved. This account they declare themselves anxious to provide, and they certainly go far towards achieving this aim. Their views and practice are, generally speaking, strictly orthodox. They do not approve of high anæsthesia, reducing the use of spinal anæsthetics generally to operations below the umbilicus. They disapprove of barbotage, and they recommend fine needles and slow injection. They depend on amount injected and force of injection for the degree of anæsthesia to be obtained. The interesting and novel suggestion is made that perhaps in the last analysis the phenomena of spinal analgesia will all be explained on an electrical basis. The vomiting, which is not uncommon some 20 minutes after injection, these authors attribute to action of the injected drug on the vomiting centre, an opinion contrary to that generally advanced in this country. Their routine drug is novocain, which they use generally in an 8 per cent. solution, and inject preferably in the fourth lumbar space. The book is written with lucidity, and any anæsthetist should read it with pleasure and advantage.

REPORTS AND ANALYSES

SOYOLK.

(THE SOYA FLOUR MANUFACTURING CO., LTD., 7, MINCING-LANE, LONDON.)

"SOYOLK" is a pale yellow, very finely ground flour, prepared from the Soya bean by the Berczeller process (Eng. Pat. 234,202 of 1924), the beans being first heated in a dry state, then agitated and subjected to the action of low pressure steam. This amounts to a partial cooking process, and the resulting flour, whilst retaining the high nutritive value of the original beans, loses the characteristic rather harsh raw flavour.

When analysed the following results were obtained:

Moisture	7·3	per cent.
Fat	20·0	,,
Protein	43·5	,,
Mineral salts	4·7	,,
Phosphoric acid	1·44	,,
Lecithin phosphoric acid	0·16	,,
Fibre	1·38	,,
Cane sugar	10·50	,,
Other carbohydrates	10·10	,,

The nutritive value of "Soyolk" is very high, the conventional calorie value being 449 per 100 g., whilst that of a wheat flour is 360; nearly nine-tenths of the protein in "Soyolk" is soluble in pepsin hydrochloric acid.

The Soya bean is a well-known food material in the far East, and its introduction to the Western hemisphere is a useful addition to our food-supply. Hitherto the principal objection has been the rather unpleasant flavour, but this appears to have been eliminated in "Soyolk." It is interesting to note that some authorities claim that the protein in the Soya bean is one of the few vegetable proteins which, to a great extent, are capable of substituting meat proteins.

THE LANCET.

LONDON: SATURDAY, JULY 5, 1930.

DISINFECTION.

THE first volume of the Medical Research Council's "System of Bacteriology" is of more general interest than the four highly technical instalments which have actually been published before it. Prof. W. BULLOCH deals with the history of bacteriology with his usual accomplished mastery of the literature. Prof. F. W. ANDREWES, discusses the classification of bacteria and the criteria which give valid distinctions between genera and species, and Dr. J. A. ARKWRIGHT writes an extraordinarily interesting account of bacterial variation. Both these articles have wide biological implications, and we hope they will be read by many scientific workers who have no immediate connexion with microbiology. The same is true of the article by Miss HARRIETTE CHICK, D.Sc., on the theory of disinfection, which not only indicates how practical people may use disinfectants to the best advantage, but opens up the great problem of how animals are killed by harmful conditions of the environment, in other words, the principles of mass destruction through which natural selection operates. We wonder whether these products of the bacteriological laboratory are as familiar to general biologists as they ought to be. Miss CHICK points out that, when a disinfectant is applied to a large population of bacteria, the microbes are not all killed at once. The killing process takes time, even if that time is very short, and if the disinfectant is strong enough to kill the great majority in a minute or two it will hardly succeed in killing all of them in half an hour. If the killing time is reduced by increasing the strength of the disinfectant, or by raising the temperature at which it acts, the same relation holds; some microbes still survive much longer than the majority. Incidentally, we suspect that the influence of high temperatures in increasing the efficacy of disinfectants is hardly sufficiently realised except perhaps by those who insist on having hot water to wash their hands with; the killing effect of carbolic acid is enhanced about ten times by a rise of 10° C., and soap, at the hottest temperature which the average hand can bear (a little below 50° C.), is probably three or four times as fatal to micro-organisms as it is at body temperature. The killing being in all cases a time process, it cannot be as correct as it is convenient to talk of this or that organism having a certain "thermal death point"; all that is really ascertained is that at a given temperature, &c., a certain proportion—e.g., 90 per cent.—of the individuals are dead at the end of a certain time.

So much for the immediate practical applications. The more detailed analysis of this time process takes us into the fundamentals of life. It is found (and Miss CHICK herself has been mainly responsible for the discovery) that the individuals in a uniform population of bacteria die logarithmically, which is to say that if 50 per cent. die in the first minute of disinfection, 25 per cent. will die in the second minute, 12½ per cent. in the third minute, and so on; the number which die in any interval of time is always a constant proportion of those alive at the beginning of the interval. The extraordinary thing is that this is just the way in which molecules of cane sugar break up when they are boiled with hydrochloric acid, with the implication that the whole of the microbe is analogous to a molecule. Prof. A. E. BOYCOTT commented some time ago on the significance of this analogy in our conception of the units of which the world is made. It may be—the suggestion was made too recently to be incorporated in the article—that the death of the organism is determined by the destruction of some one particular molecule. This would, perhaps, make the analogy easier to accept, but it would leave the explanation of the facts where it is, since physical chemists can "explain" the behaviour of the cane sugar molecules only by assuming that they are subject to rhythmical changes in susceptibility to hydrochloric acid. This logarithmic process of death is also flatly discordant with the general rule that all measurable qualities of live organisms are distributed on something like the normal curve of variation. If resistance to disinfectants varies on the same plan as human stature or the diameters of blood corpuscles, there should be a few very susceptible organisms and a few exceptionally resistant, with the majority in intermediate positions. Killing off a population like this does not give a logarithmic curve, but one in which the rate of disinfection increases as the process proceeds. And it is necessary to note that though the logarithmic result has been obtained in a majority of the most careful observations, a result compatible with the normal curve of resistance has been reached several times. The logarithmic death-rate is, therefore, not an invariable rule, and Dr. HENDERSON SMITH has published figures which indicate that the mode may vary with the strength of the disinfectant.

The matter is puzzling enough, and Prof. C. EIJKMAN made it more curious when he discovered that bacterial spores germinate in the same logarithmic fashion. But there is no doubt about the fundamental importance of the problem, and the more people puzzle about it the better. They cannot do better than start with Miss CHICK's summary account.

THE I.M.S. AND THE SIMON REPORT.

IT is chiefly through the medium of the Indian Medical Service, which still contains a large British element, that this country has come into touch with medical affairs in India, and the future of that service is a matter of concern not only to those who are serving and those who contemplate

entering the service, but to all who are following the progress of medicine in the East. Doubtful or undesirable conditions of service would lead to an increase in early retirement, and to an accentuation of the shortage in recruiting which is already pronounced enough to give cause for anxiety. The proposals contained in the report of the Indian Statutory Commission are, as has been emphasised by Sir JOHN SIMON, merely recommendations; but even should they not be adopted, they cannot fail to influence future developments, for good or for ill. The most explicit reference in the report to the Indian Medical Service deals with the provision of European medical officers for the medical treatment of European members of the services in general and their families. This consideration has been repeatedly stressed by previous commissions, and the present report insists that no efforts should be spared to secure an adequate number of suitable recruits for the purpose. In other directions there have been many proposals during the last 40 years for the reorganisation of the Indian Medical Service; some of them have contemplated a separation of the civil branch of the service from the military, others a decentralisation of the civil side and the substitution of provincial services. Logically there was much to be said for several of these schemes, but the fact remains that all of them have so far been rejected on account of obstacles, insignificant enough in appearance, but apparently insuperable.

The crux of the problem at the moment, and the consideration which is most likely to affect recruiting, is the question whether the remaining civil appointments are to be dealt with on a central basis, in association with the military branch, or whether they are to be provincialised. On this the report sheds some light, if only indirectly. The Commission recommends that the Secretary of State should still retain power to prescribe the number of I.M.S. officers to be employed in the provinces, as well as the appointments and conditions upon which they shall be employed. This would seem to imply continuance on an all-India footing; and indeed many of the contentions in favour of all-India recruitment for the so-called security services, which include the civil service and the police, as well as for irrigation and forestry, would equally apply to medicine. It is argued with justice that an imperial service appeals to a large circle of candidates, while the status and tradition attaching to it draws recruits of a superior class. The recommendation of the Lee Commission that medical officers recruited on an all-India basis should continue to be employed in the provinces to maintain a war reserve is also cited, apparently with approval; it is pointed out that if European recruitment for irrigation, for example, were conducted on provincial lines, it would probably be on short-time contracts, involving risk, from an administrative point of view, that would be hard to justify. Precisely the same would apply to the I.M.S. It has been suggested that provincial ministers might be hampered in carrying out their duties by the limitations upon their control over members of the all-India services. In practice this has not been so. Evidence was given by these ministers before the Lee Commission that, with negligible exceptions, all-India officers serving under them had given their loyal support. No doubt the converse for the most part holds good, although there is an unfortunate impression in certain provinces that ministers in transferred departments (of which medicine is one) are apt to interfere unduly in detail. This tendency would certainly not be diminished by provincialisation.

If the right kind of recruit is to be attracted to medical service in India it is at the present juncture more than ever necessary to avoid any action which would tend to neutralise the improvements in the terms of service which have been lately introduced. Among other things these include, as our readers are aware, passage concessions, overseas pay, and reservation of certain posts. As regards existing members of all-India services, including the medical, the Commission appears to have done all that was in their power to safeguard their position. No change is to be made to their disadvantage, and they are to be entitled to any concessions that may be granted in future. A proviso is also made that retirement on proportionate pension should remain open without limit of time to any officer who might under the present rules have so retired upon the coming into force of the constitutional changes now proposed. It is recommended too that any changes in the statutory rules which concern officers now in the all-India services should only take place with the consent of a majority of the Council of India, which would, as hitherto, contain representatives of the services. There are in the report some apposite observations about the safeguarding of service pensions. It is regarded as certain that European recruits of the required capacity and character required can only be obtained on terms which give them—subject to one exception—the same rights, privileges, and safeguards as have been awarded to the present members of the services. The exception is the right of premature retirement, and it is an important omission. The difficulty is partly met, however, in the case of the I.M.S. by the system of optional retirement, with gratuities, after a certain number of years. If the assumption on which these observations are based is justified, it would appear that the I.M.S. has little to fear from the recommendations of the Commission. It is true that with progressive Indianisation the European personnel in all departments is likely to shrink still further, but for the present at all events the medical service is less likely than any other to be affected, and most other adverse influences have been discounted in advance. Few would be bold enough to forecast what political and other changes the next few months may hold for India, but so far as medicine in its official capacity is concerned the portents seem no worse now than they were a fortnight ago. There are so many Indians now in the service that the racial aspects, from which it has been so acutely surveyed in the past, will no longer afford the logical method of thinking—the service as a whole and not its racial make-up has to be regarded.

GLANDULAR FEVER.

THOUGH not a rare disease, glandular fever is often overlooked. At present it seems to be pretty widespread in this country, and though the cases mostly conform to type, there are several variations which may darken judgment. As first described by PFEIFFER, in 1889, it is an epidemic infection, tending to affect children and young adults, and its characteristic features are pyrexia, enlargement of lymphatic glands, and slight constitutional disturbance. H. LETHEBY TIDY and E. C. DANIEL, reviewing the subject in our columns[1] a few years ago, said that as a rule the onset is acute with malaise and fever, and that the temperature, though it may rise to 103° F. or higher, is usually in the neighbourhood of 100°. The glands commonly begin to enlarge within the first week, often at the third or fourth day, but in the present epidemic there has sometimes been no swelling until the fourteenth day, or even much later. The cervical and occipital glands are most likely to suffer, and they may be greatly swollen and tender on palpation. The enlargement, like the fever, may last many weeks, but usually the symptoms subside within a month. Many of the contemporary cases are running a long course, and often either the fever or the glandular swelling is relatively slight. A rash has been noticed in a fairly large proportion, and some have been recorded at first as examples of "an obscure exanthem."[2] In our present issue Dr. MAITLAND RADFORD and Dr. J. D. ROLLESTON describe two cases in which the rash resembled that of typhus. Apparently it is apt to appear in crops between the fourth and tenth days of the illness, and it may simulate the rose spots of typhoid. GEOFFREY EVANS and W. A. ROBB[3] have observed urticarial, macular, and papular eruptions, but while all these may lead to mistaken diagnosis it cannot be said that any rash at all is characteristic of the disease.

Lymphocytosis and splenomegaly are neither of them quite constant features of glandular fever, but a certain amount of enlargement of the spleen is usual, and there is nearly always an increase of lymphocytes in the blood, both absolute and relative. The total number of white cells is commonly about 10,000, but may rise as high as 25,000, and the bulk of them are large mononuclears with big pale nuclei and large amounts of protoplasm. There is no anæmia. The blood picture may thus be exactly the same as in the condition described as infective mononucleosis by SPRUNT and EVANS,[4] and variously recorded as pseudoleukæmia or as "acute lymphatic leukæmia with recovery" by older observers. The two diseases—glandular fever and infective mononucleosis—are now regarded as identical. The lymphocytosis is, of course, an important diagnostic guide, and the main points to look for are thus: (1) fever with little constitutional disturbance; (2) enlarged and tender glands, often with a palpable spleen; (3) lymphocytosis without anæmia; and (4) occasionally an indefinite rash. Tonsillitis is absent, though the fauces may be reddened, and the parotid is not involved. In an epidemic these features make the diagnosis relatively simple, but this is by no means true of isolated cases. The greatest difficulty lies in differentiating the condition from a "pyrexia of unknown origin" and from the typhoid and paratyphoid group of infections. In the latter the absence of lymphocytosis, a positive blood culture or Widal reaction, and a much greater constitutional disturbance may serve to make the distinction. In rubella there is no splenic enlargement, the glandular swelling is transitory, and the rash is immediate, whilst mumps, and septic glands due to tonsillitis and the like, should be readily identifiable. Glandular fever is unlike leukæmia in that it does not cause the same degree of illness and there is no anæmia. The glands may feel like those of Hodgkin's disease, but are nearly always tender; they are never known to suppurate like septic glands or caseate like tuberculous glands.

Of the ætiology of glandular fever little is definitely known. The disease is unquestionably epidemic, but is not very contagious, and patients can be safely nursed in a general ward. Spread in schools and institutions is more probably attributable to a common source of the infection than to direct contagion. The incubation period has been placed at between five to seven days, but is now thought to be considerably longer, and may well be four or five weeks. The only common sequela is a period of depression—similar to that which follows influenza. Nephritis has been mentioned as a complication, but is always unusual and is extremely rare in the present epidemic. The treatment is purely symptomatic.

THE BREEDING OF MAN.

THE opening took place this week of the Animal Breeding Research Department in the University of Edinburgh, the formal declaration being made by Sir EDWARD SHARPEY-SCHAFER, emeritus professor of physiology in the University. Sir EDWARD in his address took for his text the words appropriately placed by Prof. CREW, the Director, over the entrance: "To the Advancement of Science and the Service of Mankind"; he eloquently outlined the position in which scientific genetics now stand, while with grave but amusing malice he ruled the opponents of physiological research out of any court where reason may be the judge or humanity the jury.

The department was established ten years ago, with the function to investigate the principles governing the breeding of animals employed in agriculture, but, Sir EDWARD pointed out, though primarily the encouragement of agriculture under the auspices of the relevant Government bureau had been the objective, the far-sighted view had been adopted of applying the lessons to be learned from the breeding of animals, small and large, and of plants, to the betterment of man's pedigree; while he pointed out that the direction of such studies could have fallen into no better hands than those of Prof. CREW, an opinion that will be

endorsed by all who are familiar with the Professor's text-books, or have personal knowledge of his learned enthusiasm. Sir EDWARD'S main thesis was that the principles of genetics, as we now begin to understand them, are found applicable to all animals and to all plants; the lessons derived from their study can be applied to man, so that knowledge acquired in the breeding of the horse, the fly, or the sweet-pea can be, and should be, utilised for the improvement of the human race, with the outcome that much which tends to depress that race, physically and mentally, may be eliminated. Deliberately passing over the question of birth control, he pointed to the dependence of the study of animal genetics upon physiology and biochemistry, and proceeded to explain in a vivid manner to a general audience the part played in the production of sex-characteristics by specific chemical substances circulating in the body. His main example of such influence was that of the pituitary body whose physiological activity he described as a romantic interlude, comparable, though scientifically true, to the adventure in "Alice in Wonderland," where the heroine grows larger or smaller in accordance with a definite vegetable dosage.

Civilisation cannot, at any rate yet, envisage organised endeavours to promote amelioration of the race by breeding from the highest types, while the study of eugenics reveals to us the grave risk that inferior stock may impede progress by its comparative prolificity. Meanwhile the problems, whose existence is thus implied, grow more complicated. For this reason, the hard work, with its large outlook, that is now being carried on at Edinburgh, deserves the attentive approbation of all. The breeding of man is not necessarily declared to be a mere matter of physiology, because we can see that in such physiological research as Prof. CREW and his staff are carrying on there lies a great possibility of increasing the happiness of the world. Although man may be more than an animal, there is every reason why his plight as an animal should be improved. Certain it is that any other qualities in his make-up will share in the story of development.

ANNOTATIONS

CRIME.

THE newly issued Criminal Statistics [1] for the year 1928 teach, among other lessons, the heavy price which the community has to pay for the lunatic at large. Out of 909 criminal lunatics under detention at the end of the year, no fewer than 405 had been charged with murder. In 1928 there were 56 persons arrested for the murder of victims aged 1 year and over; 9 of these 56 were found insane on arraignment (i.e., unfit to plead), and 11 were found "guilty but insane." The need of earlier diagnosis and earlier treatment is an obvious inference. Out of a total of 150 criminal lunatics received into asylums during the year in question, 54 had been found by juries to be either insane on arraignment or "guilty but insane"; only five of the remaining 96 had been certified insane before trial; 91 were certified insane while serving sentences in prison. It is hard to resist the impression that there was waste of time and money in trying persons who were already insane. The criminal law really ought to enlarge its ancient view of responsibility for crime. It should learn to recognise mental disease as a condition of perhaps long and gradual development rather than to contemplate only the sudden aspect of 100 per cent. insanity. Is it reasonable to suppose that the insanity of those 91 persons was not to be detected without first sending them to prison as convicts? After giving a comparative table of figures for 1911 and 1928 to show the sentences passed for indictable and non-indictable offences where delinquency was associated with mental impairment, the report observes that there were also many cases where, because the condition had not been diagnosed, or for other reasons, the certifiable mental impairment did not appear until the person had been sentenced. "In some of these cases the persons were removed to asylums as criminal lunatics; in others to institutions for mental defectives; but the shortage of accommodation for the latter often caused delay. If more accommodation was available and was utilised at the outset, fewer mentally deficient persons would commit offences, come before the courts, and raise the vexed question of sterilisation." This is a shocking admission by the department responsible.

The general tenor of the introduction to the statistical tables is of great interest. The Home Office, if it has to disclose increased figures for certain crimes, naturally does not want us to think that the police, the magistrates, the law-courts, or the administration are failing in their duty. Thus we are warned against fluctuations which may be purely statistical. Are more crimes reported? It may be because the police are becoming more vigilant, or because victims more willingly come forward, or because the popularity of insurance leads to more frequent complaints of loss or damage as a preliminary to a claim on a policy. In the general class of sexual offences, the figures for the full offence of rape and for the defilement of girls under 13 are lower. Here, the report suggests, the lower totals represent a genuine decrease in crime. On the other hand, the apparently serious rise in indecent assaults and the defilement of girls from 13 to 16 may, urges the official apologist, be due to a change in the moral outlook and to the greater interest taken by women in all that concerns their sex. The suggestion that women are now more ready to report sexual offences will, however, hardly explain the increase in offences between males. There seems to be a sharp rise in the offence of procuring abortion. The suicide figures are down, for the first time since the war; but attempted suicides are up. Comparisons here must be difficult, since it is the modern policy not to take proceedings for attempted suicide unless detention for a time is in the person's own interest or for other sufficient reason. The kind of offence which evilly disposed or mischievous people commit with the aid of motor-cars (often stolen) has increased sensationally—the smash-and-grab raid, bag-snatching and burglary, and house-breaking. The last-named offence seems to be committed with a certain impunity in country districts. Comparative annual totals

[1] H.M. Stationery Office. Cmd. 3581. 4s.

require, of course, to be coördinated with fluctuations in the population. The effect of the Criminal Justice Act of 1925, which enabled many offences to be disposed of summarily instead of being tried by indictment, is not easy to estimate. The official introduction furnishes useful material for attempting to understand the effect of education, the effect of the war, and the effect of shorter sentences; there is also some examination of drunkenness in relation to crime. The conclusions may not be universally accepted, but the figures cannot be ignored by the student of social conditions.

EFFECT OF IRRADIATION ON RESISTANCE TO INFECTION.

IN the June issue of the *British Journal of Experimental Pathology* Sir Leonard Hill, Prof. M. Greenwood, and Prof. W. W. C. Topley describe an experiment designed to test upon a numerically adequate sample of animals exposed to infection whether irradiation confers any immunity from fatal infection. Starting on April 24th, 1929, an infected herd was formed by inoculating 25 mice with pasteurella and adding them to 100 normal mice, housed in the type of cage employed in the study of experimental epidemics. Thereafter, three normal mice were added to the cage each day. By May 5th all the inoculated mice were dead, and no effective spread to the contact mice had yet occurred. On that day a second batch of 25 inoculated mice were added to the cage. Within the next few days some of the contacts died of typical pasteurellosis, and on May 15th the experiment began by the daily addition of three irradiated mice at the same time as the three regular controls. The treatment of the irradiated mice was as follows. The lamp employed consisted of a frosted vitrosil tubular mercury-vapour lamp, screened by a sheet of glass permeable to ultra-violet rays up to 2850 A.U., but not to shorter rays, along which on either side was placed a row of incandescent lamps sufficient in number to balance the blue light coming from the mercury-vapour lamp and produce colours—e.g., of flowers, equivalent to those produced by sunlight. The animals were placed in cages four feet below the lamp and exposed to the light for 48 hours. A fan was kept running to keep the cages cool. The cages were at first covered with gauze which allowed about half the light to penetrate; later this was done away with, and on July 17th the screen of glass was removed from the lamp to allow shorter ultra-violet rays to pass. The change did not alter the negative character of the results. On August 22nd six normal controls and no irradiated mice were added but, with this exception, there was no departure from the rule of adding daily three of each class. On Oct. 30th the last batch of immigrants was added, and on Dec. 31st the surviving members of the colony were killed. The tables supplied of the general vital statistics of the community show that the course of events differed in no significant way from that usually observed in such colonies. The planning of the experiment admitted of a direct comparison of the fates of normal and irradiated mice. Thus of the entrants to the community down to July 16th there were 189 irradiated and 189 normal mice admitted on the same days, and all of these died before the experiment was brought to an end. The mortality of the irradiated mice from the specific infection was insignificantly less and from other causes insignificantly greater than that of the control mice. The average lifetime of the controls was rather greater, when all causes of mortality were considered, than that of the irradiated mice. When mortality from all causes save the specific infection was ignored the two expectations of life were identical. It is clear that in this experiment, which involved the use of more than 1000 mice, irradiation conferred no advantage upon the treated animals in respect of the hazards to which they were exposed. To the possible criticism that the mice were not shaved the authors have a cogent answer: exposure of the naked parts of the head and feet to irradiation suffices to protect young rats fed on a rickets-producing diet against rickets, and it would therefore seem probable that the mice used in this experiment received an effective exposure, so far as the antirachitic effect can be accepted as a criterion of adequate dosage.

These negative results of irradiation with mice correspond with those of guinea-pigs recorded in the annual report for 1929 of the Lister Institute of Preventive Medicine. A pneumococcal infection among the breeding stock of this Institute, to which reference was made in the report for 1928, still persists, though not to any serious degree. A statistical analysis of the results of irradiating one-half of the breeding stock by means of a mercury-vapour lamp during a period of 12 months has been completed with the coöperation of Dr. P. L. McKinlay. No evidence was obtained that irradiation reduced the incidence of the infection or had any beneficial influence upon the general health and fertility of the animals.

The question whether exposure to ultra-violet light has any general beneficial action on the animal or the human body, apart from its specific effect on rickets, is still hotly debated, and more controlled investigations of this kind are needed. That benefit is felt by individual patients is undoubted. But, as with Hamlet's ghost, the problem whether the phenomenon is objective or subjective remains unsolved.

LIVER EXTRACTS IN DIABETES.

THE surprising success of oral administration of liver in pernicious anæmia has naturally fostered the hope that other diseases might respond to this treatment. Some 12 months ago H. Blotner and W. P. Murphy observed that liver, in spite of its relatively high content of carbohydrate and protein, is capable of lowering the blood-sugar when administered by the mouth, and they now record [1] further experiments bearing on the nature and action of this hypoglycæmic principle. In a series of diabetic patients they have studied the blood-sugar curve under the following circumstances: (1) after administration of extracts of liver treated in various ways; (2) after hypodermic injection of insulin; and (3) without insulin or liver extract. The curves were constructed from blood-sugar readings taken immediately before and at intervals during eight hours after a fixed meal consisting of 20 g. carbohydrate, 40 g. protein, and 35 g. fat. They find that an aqueous extract, prepared by soaking pulped liver in water at pH 4·6 to 5·2, and at a temperature of 35–40° C., contains the active principle which lowers the blood-sugar. Evaporation of this extract to a paste or a powder at 80° C. does not destroy the active principle, but exposure to heat above 80° C. causes it to deteriorate rapidly. They also observe that a precipitate forms after heating an aqueous extract at 80° C. for a few minutes, and that this precipitate contains almost the whole of the active principle. Incidentally, since the precipitate contains

[1] Jour. Amer. Med. Assoc., June 7th, p. 1811.

no sugar, while the supernatant fluid contains an appreciable quantity, this furnishes a simple method of getting rid of the undesirable carbohydrate. The effect of liver extracts on the blood-sugar is by no means startling. The equivalent of 500 g. of liver has roughly the same effect as 10 units of insulin, and the symptoms of hypoglycæmia have not, so far, been observed. Moreover, a lowered blood-sugar does not of necessity imply that the patient is receiving benefit. Nevertheless, it seems likely that liver extract will prove to be of practical value. In the severe grades of diabetes it may never be more than an adjunct, but perhaps the concentration can be further increased. The necessity of giving insulin by injection is a disadvantage which everyone is anxious to avoid.

THE TRADER'S ACCESS TO THE TOWN DRAIN.

APPOINTED in November, 1927, the Joint Advisory Committee on River Pollution published in the following July its first report [1] dealing with the question of machinery and of the units best adapted to enforce the prevention of pollution. Its second report [2] deals with the problem of trade effluents in local sanitary authorities' sewers. The recommendations are based on existing provisions in local Acts; as is well known, experiments in public health and other matters are often given a local trial and found worthy of more extended application. The Joint Advisory Committee comes out frankly in favour of giving the trader a definite right to discharge his effluent into the sewers and of requiring the local authority to receive and dispose of it. This is the principle introduced in the Halifax Corporation Act of 1905 and various other local statutes since then. Certain substances are still to be excluded from the sewers; petroleum-spirit and liquids of abnormally high temperature cannot be received without risk of danger and nuisance. This exclusion, it is proposed, should be strictly maintained as contemplated by the existing general law. The local authority by a system of agreed local regulations is to secure that the effluent received shall be tractable and that the necessary sedimentation or other preliminaries shall occur before discharge; it is to have power to regulate the rate and volume of discharge, to impose reasonable charges and to provide for measuring quantities, inspecting effluents and taking samples. The local authority is also to have power to remove sludge or other deposited matter from the trader's premises; such matter will be produced in complying with the regulations and the removal of it is a service for which the trader is expected to be willing to pay. Among consequential recommendations is one to permit the local authority to enter into special agreements with individual traders. Existing written agreements for disposal of effluents for valuable consideration are to be safeguarded, and, where any trade effluent is already discharged into the sewers, the trader is to be deemed to have required the local authority to receive and dispose of it under the new principle. If capital works are necessary on the trader's premises to enable him to carry out preliminary treatment, the report suggests that local authorities be allowed to undertake such works on request and at his cost, and to advance him the amount of the expenditure on terms to be agreed. An excellent point here is that, if the trader provides works on his premises for the preliminary treatment of his effluent, in order to comply with the local authority's regulations, he ought not to find that his costs of production are thereupon increased by the increased assessment of his premises for rating purposes.

The exact purport of the Committee's present recommendations can be seen from a set of draft clauses appended to the report. They are not framed as a draft Bill and they are not to be taken as the last word in verbal form, but they are a useful summary. The report recommends fresh legislation of a universal and not of an adoptive nature. Local authorities may find it desirable to combine for these purposes and this they will be encouraged to do. It seems reasonable to hope that the new plan will have a better aggregate effect on the river. Efficiency ought to be greater if treatment is concentrated in a single centre under the control of the local sanitary authority. The present scattered system expects a number of manufacturers to purify their effluents separately; but their interest is in manufacture not in sewage disposal, and a small factory with a moderate daily volume of effluent often cannot afford a whole-time qualified staff for purification. Plainly the treatment and disposal of trade effluents should be the normal function of the local sanitary authority which already must receive and dispose of domestic sewage. Moreover, in a few cases the chemical or bacteriological nature of the trade effluent causes treatment to be cheaper and more efficient if there is dilution with ordinary domestic sewage. The crux of the new plan is to get rid of Section 7 of the River Pollution Prevention Act of 1876 and to clear away legal entanglements by giving the trader the right to discharge his effluent while obliging the local authority to receive and dispose of it. The idea is worth trying. It will give anglers new hope, while the general public may expect some restoration of ancient amenities even if their rates will cost them more, and the cause of public health should be served.

PROGNOSIS IN MENTAL HOSPITALS.

THE ability to forecast the fate of a person entering a mental hospital is important not only for the patient and his friends, but also for the administrators, who have to study their future accommodation. The State Charities Aid Association in New York has investigated the expectation of hospital life on first admission, and Dr. R. G. Fuller reports [1] on the fate of six groups, each of 600 male and 600 female patients, representing consecutive first admissions over a varying period beginning on Oct. 1st, 1909. The six groups chosen were manic-depressive, dementia præcox, senile, arterio-sclerotic, alcoholic and general paralytic, as the most important numerical groups in the State hospitals. All the cases have been observed over at least 15 years, and the results are set out in six statistical tables showing the number still in hospital, the number discharged, the number dead, and the relative proportions. It appears that more than half the general run of mental patients are out of hospital within a year of their admission, and that nearly three-quarters leave within five years. The manic-depressives seem either to be discharged within three years or to remain the whole period of 15 years. More than half the manic-depressive, senile, arterio-sclerotic, and alcoholic patients are out of hospital, either dead or discharged

[1] Psychiatric Quarterly, April, 1930.

at the end of nine months, though of course some of those discharged will return. As would be expected, the dementia præcox patients show the greatest proportion remaining in hospital at the end of a year; more than two-thirds of them fail to obtain a discharge. In every group there is a slowing of the rate of reduction in the number of patients in hospital in succeeding years. The first-year drop is a sharp one, the second year's is also sharp, and the rate gradually decreases to the end of the fifth year. From that point a reduction is extremely slow for general paralytics and manic-depressives, and for all groups it is slower in the second five years than the first. The great diminution in the numbers of senile and arteriosclerotic patients in hospital throughout the whole 15 years' period is largely due to the high death-rate; discharges are relatively few. The number and proportion of women exceeds that of men for every period and group, the difference being most marked in the senile group. A remarkable number of manic-depressives die soon after their first admission, though their prospects of recovery and permanent discharge are much better than those of the dementia præcox cases. These show about the same death-rate at the end of the period, having made it up in later years. Female deaths exceed male deaths at every period in the dementia præcox group. As is well known to psychiatrists, there are more permanent discharges in the first year than in all the succeeding 14 years. Further comparisons and contrasts might be drawn from these tables; the figures on the whole serve to prove the well-known facts of mental hospital life.

THE HYGIENE OF MENSTRUATION.

SIX thousand replies have been received to a questionaire on menstrual experience issued either directly, or through parents or teachers, to girls attending day and boarding schools in Great Britain by the London Association of the Medical Women's Federation. The correlation on statistical lines of the information received has been laborious, especially since the questions were framed under peculiar difficulties. In order to avoid disturbing the children no detailed questions were permitted, and such interesting matters as the age of onset, the presence of menorrhagia, and the type and site of pain could not be ascertained, though some children gave unsolicited information that the pain was slight or severe. Especially in those who complained of pain *after* the period the suspicion arises that local discomfort, smarting, or soreness, may have been meant, rather than abdominal pain. The most important practical point which arises from the inquiry is the need for better provision of facilities in schools and even in pavilions of playing fields for menstruating girls. The reticence about the hygiene of the menstrual period among women of all ages has been, and still is, a grave handicap in the way of abolishing bad traditions and of teaching young girls a régime conducive to health and comfort. The prejudice against baths during the period is only being broken down slowly, and the necessity for increased rather than diminished cleanliness at this time has hardly yet spread among the less educated. Nor is the young girl always properly taught to avoid the chafing which is often an intolerable plague to the schoolgirl. This may be particularly troublesome to the girl with a profuse flow, to the stout girl, or to the quite considerable number in whom the period is accompanied by a slight bladder irritability. It may need years of experience to teach a girl that this distress is unnecessary. A bath or a wash morning and evening, the use of simple dusting powders or ointments, and the selection of a soft material for the diaper should prevent any local irritation, more especially if a change of towel is available in the day time. Facilities have been immensely improved of recent years in factories, thanks mainly to the welfare workers during the war, in public lavatories at stations, in large shops, &c., and even in offices where large numbers of girls are employed. Slot machines, with enamelled bins for the disposal of soiled towels, are now found in many such lavatories, to the immense benefit of women clerks and shop girls. The schools and playing fields lag behind in this respect. Even such trifles as the use of an elastic rather than a rigid belt to hold the towel should be gone into. A further point of importance is to convince mothers and girls that menstruation ought not to be disabling, and that if it is treatment should be sought and persevered in as for any other ailment. Oddly enough, in spite of all experience to the contrary, many women still think that pain and disablement at this time are a rather meritorious and interesting sign of femininity, and they resist all suggestions for treatment. The fact that pain seems to become more common as the girl grows older adds point to the suggestion made in the report that the inquiry ought to be pursued to cover women over 18. The questionaire might be made more precise when the limits of menstrual disability could be more readily ascertained. Girls living at home, students at universities, nurses working in hospitals, and women employed in business would form suitable groups. It is to be hoped that the London Association of the Medical Women's Federation will pursue their inquiries under expert statistical guidance.

HOME SERVICE AMBULANCES.

THE service of ambulances established by the Order of St. John and the British Red Cross Society, and now entering on its twelfth year, has justified its existence 847,065 times since its origin, by transporting that number of persons to hospital or to their homes. At the present time 343 stations form a chain of service from Northumberland to Cornwall, and though the committee makes no claim to perfection as yet, a steadily increasing number of calls are being met by a gradual extension of the service. The aim is to provide transport for the sick and injured in those districts of England and Wales where no other service is available, but with the rapid increase of motor traffic the ambulance is most frequently in demand for cases of accident. The work of the ambulance service in these cases is supplemented by the first-aid given at dressing stations, and by the voluntary assistance of members of the Order and the Society who patrol the roads during week-ends and bank holidays. First-aid boxes are being set up by the roadside in large numbers, and members of the St. John's Ambulance Brigade and the British Red Cross Detachment living near main roads are urged to keep a supply of dressings in readiness. A mobile X ray department has proved useful in those cases where removal to hospital or to an X ray installation is inexpedient. The plates are developed immediately in the dark-room of the car, and are later submitted to an expert radiologist. The only charges made for the use of ambulances are sufficient to cover the running costs and maintenance, with a small contribution towards a sinking fund for

their replacement when worn out; the members of the Order or the Society who staff the ambulances give voluntary service. Grants are given towards the cost of providing ambulances at the request of county representatives, and subject to certain conditions of maintenance and insurance. When it is remembered that 170,000 persons were killed or injured in road accidents during 1928, and that there is every possibility that this number will increase for some years to come, the extension and perfection of this ambulance service becomes a matter of individual concern.

THE TREATMENT OF VENEREAL DISEASE IN THE EAST END OF LONDON.

IN 1914 the treatment of gonorrhœa in a systematic manner was first undertaken by Mr. Frank Kidd in a very small room in the out-patient department of the London Hospital. The work was not at first officially recognised, but nevertheless it rapidly attracted a large number of patients. Mr. Kidd was assisted at first by Mr. E. C. Lindsay and Mr. G. Neligan, and later by Mr. R. Love and Dr. E. R. T. Clarkson. In 1917 a department for the treatment of gonorrhœa was officially instituted under the supervision of Mr. Kidd as chief of the Genito-Urinary Department. Dr. Malcolm Simpson was appointed chief clinical assistant in the women's section, and Dr. Clarkson chief clinical assistant in the section for male patients. In 1920, owing to the resignation of Mr. Kidd from the staff of the London Hospital, Mr. Hugh Lett became surgeon in charge of the Genito-Urinary Department and also director of the gonorrhœa section. The junior clinical assistants during the régime of Mr. Kidd were deliberately selected from the ranks of general practitioners and of London Hospital men who had recently qualified. The average number of junior clinical assistants was usually two in the female and five or six in the male section. Dr. W. S. Dwyer acted as registrar of the male section. The bacteriological work was carried out in the clinical laboratory of the hospital and in the bacteriological laboratory. Important changes in this centre have now been made. On Jan. 1st, 1930, Dr. Malcolm Simpson and Dr. E. R. T. Clarkson resigned their posts as senior clinical assistants but continued to work in an honorary capacity until April 1st. After prolonged negotiations, of a very involved nature, the annual grant of several thousands of pounds, contributed by the London County Council towards the work of the clinic carried out under the auspices of the London Hospital, was withdrawn, and we understand that on July 1st, 1930, the clinic ceased to have any direct association with the London Hospital. It has been taken over and staffed by the London County Council as an "ad hoc" institution for the treatment of gonorrhœa and syphilis under the directorship of Dr. T. Anwyl Davies, formerly senior assistant to St. Thomas's Hospital venereal disease department. Dr. Anwyl Davies has appointed as his senior assistants Dr. A. J. King on the male and Dr. N. Mascall on the female side, with two junior assistants, and the pathological work of the clinic will be done by Dr. I. N. O. Price. The clinic will continue to be housed in the lower storey of a block of buildings recently erected by the London Hospital, the upper part of which is occupied by house officers and the domestic staff. The L.C.C. will pay rent to the hospital for the use of the premises which will be supplied with a new entrance leading into a side street adjacent to Whitechapel-road. Henceforth the clinic will be known as the L.C.C. Venereal Diseases Clinic at the London Hospital, Turner-street, Mile End, E.1.

THE EFFECT OF SAVING INFANT LIVES.

OUR success in the fight against infant mortality has certain conspicuous gaps. Speaking at the opening session of the National Conference on Maternity and Child Welfare at Friends House, London, on July 1st, Miss Susan Lawrence, M.P., described it as having a patchy distribution over the country, while Dr. T. H. C. Stevenson explained that neonatal deaths, which are less influenced by environment than the later deaths, are highest in rural districts, with a progressive improvement up to county boroughs. The inclination to regard reduction of the early infant death-rate as hopeless, he said, is not justified. The death-rate of the first month has already been brought down from 40 per 1000 in 1906 to 31 in 1928, while in the latter year Bath had a neonatal death-rate of 22, as compared with Walsall's 50, which showed that these deaths were not inevitable. Mrs. C. B. S. Hodson pleaded that infant mortality should be considered as part of a longer curve of mortality. From a biological point of view, she said, stillbirths and natural abortions cannot be separated from early deaths. Two factors always enter in—viz., constitution and environment—and there may be a point beyond which it is impossible or inadvisable to reduce early infantile mortality. Not only is a drop in birth-rate always accompanied by a drop in infant deaths, but there is a higher incidence of natural abortion and stillbirths for every parity. The interval between births is another factor of great importance, for Woodbury's investigation showed that infant mortality was lowest where births occurred at four-yearly intervals, though personal health and circumstances must of course be considered. Mrs. Hodson aroused some controversy by stating (with statistics) that there is no evidence that reduction of infant mortality connotes a reduction in the damage rate among children. She pointed out that the number of school entrants in London who can be classified as A 1 is falling steadily, and that, comparing the years 1914 and 1926, the amount of chorea, heart disease, and rheumatism among school-children has risen by nearly one-third. She further quoted Sir George Newman's report to the Conference on Mental Health to the effect that 10 per cent. of our population shows mental subnormality of some degree, and that the only cause he could suggest was that we had been saving 40,000 babies a year. This we must continue to do, but Mrs. Hodson urged a careful use of birth control for the wise spacing of families, and of sterilisation for those evidently unfit to bear children. Dr. Harold Scurfield expressed amazement that school entrants should be found in a worse condition than formerly, but Mrs. Hodson reiterated that, speaking for London alone, though the children were heavier and better cared for, a larger proportion arrived at school suffering from some constitutional defect calling for medical attention. Dr. S. G. Moore said that an inquiry made by him some years ago had proved that there was a reduction in deaths in each of the first five years of life, and suggested that closer scrutiny might be responsible for apparently less satisfactory figures.

FAR EASTERN MEDICAL CONGRESS.—The meetings of the Far Eastern Association of Tropical Medicine are held at intervals of two or three years. The last congress met at Calcutta in December, 1927, and the 1930 congress is to be held at Bangkok, from Dec. 7th–13th. The congress will be opened by one of the royal princes who is also Minister of the Interior.

MR. C. BOWDLER HENRY:
INTERPRETATION OF
DENTAL RADIOGRAMS.

CLINICAL INTERPRETATION OF AIDS TO DIAGNOSIS

(A Series of Special Articles Contributed by Invitation.)

LXXIX.—INTERPRETATION OF DENTAL RADIOGRAMS.

(WITH ILLUSTRATIVE PLATE.)

PART I.—General Observations.

AT the outset it should be appreciated that a radiogram is but one link only in the diagnostic chain, and though it be a very important one, its value is directly proportional to its proper usage as one component of a whole. To condemn or to exonerate questionable teeth upon their radiographic appearances alone is to do so upon insufficient, and sometimes faulty, evidence.

When it is at all feasible, radiographic findings should be correlated with the results of a clinical dental examination. Dental surgeons and their patients sometimes suffer when a doctor, after a cursory inspection of dental films, expresses an opinion, often founded on an incorrect interpretation, contrary to the considered advice of the dentist. It is highly desirable, therefore, that the doctor should be versed in the interpretation of dental radiograms, so that he can correlate them with the clinical reports and decide on appropriate action. Though dental sepsis may not be sufficiently potent in a particular case to cause a secondary lesion, it is capable, even in mild degrees, of swinging the balance, and it may also put an effective drag on recuperation. Dental radiograms should therefore be taken in all cases of debility or chronic ill-health.

The practice of radiographing suspicious teeth and ignoring edentulous spaces is unwise; to take the patient's word that he is edentulous is often to miss a hidden source of focal infection. At the Mayo Foundation all patients are submitted to a dental examination, which includes a full set of films, as a matter of routine.

EXAMINATION OF DENTAL FILMS.

It is not sufficient to hold dental films casually to the light and note only the gross changes, such as impacted teeth, the outline of cysts, or the presence of obvious apical rarefaction. The films should be examined first generally by the naked eye and then critically with a lens over a suitably diffused source of light, such as an opal glass electric lamp

DESCRIPTIONS OF ILLUSTRATIONS ON SPECIAL PLATE.

PART I.

The illustrations show one-half of a fairly normal set of dental films, some examples of errors of interpretation which may arise through taking radiograms from an incorrect angle, and some teeth with caries and periodontal disease. Some of the teeth have had fillings, shown as radiopaque (white) clearly defined areas.

FIG. I.—(A) Malar process often casts a radiopaque shadow (Z) over the apices of the upper molars.
(B) The antrum, delineated by an even line (Y), is in close proximity to the premolar and molar roots. In order to display the antrum this film was taken from an angle which makes the premolars appear foreshortened.
(C) Shows the canine, lateral, and central incisors, from left to right of film.
(D) Shows anterior palatine fossa (W) in correct position between the apices of the central incisors. The nasal fossæ are in close relation to the apices of the central incisors.
(E) Shows same fossa (W) superimposed upon the apex of the right central incisor, and might be mistaken for area of rarefaction. This film, of which the left half only is reproduced, was taken to show the lateral incisor. The angulation, therefore, was incorrect for the central incisors. This shows the need for taking enough exposures to obtain correct angulation.
(F) Inferior dental canal (V) shown below apices of molar teeth.
(G) Mental foramen shown as a dark patch (U) between and below apices of first and second premolars.
(H) Lower incisors.

FIG. II.—Foreshortening of the image of the upper central incisors (the same teeth as shown in Fig. I., D) due to using too high an angle. Foreshortening and absorption with regeneration of bone are easily confused, and confirmatory radiograms are desirable in all cases where foreshortening occurs.

FIG. III.,C.—Photomicrograph of the amelo-gingival junction in a young dog. Nasmyth's membrane can be seen sagging towards the tooth, the subjacent enamel having been dissolved away. The epithelial barrier formed by the junction of the membrane and epithelium of the gingival trough is the first defence to be broken by the ingress of pyorrhœa. A = Space created by the solution of the enamel. N = Nasmyth's membrane (enamel cuticle); the membrane collapsed towards the dentine on account of loss of support when the enamel was dissolved. G.C. = Gingival crest. C.E. = Crevicular epithelium.

FIG. IV.—Upper and lower third molars (T) in a boy aged 17. Owing to lack of developments antero-posteriorly in the jaws these molars are unable to erupt into normal position. The inclination of each presents the commonest variation. The lower is locked with the second molar and has prevented it from erupting normally. This boy's only sister (older), his mother, and his mother's brother had similarly impacted third molars.

FIG. V.—The mental foramen (S) is subject to variation of position and may appear in close apposition to the apex of the second premolar simulating a pathological area of rarefaction.
The first premolar in this film exhibits an advanced stage of local periodontal disease aggravated by traumatic occlusion with the teeth of the opposing jaw. Note the loss of alveolus and the open funnel-shaped socket produced by the marginal rarefaction.

FIG. VI.—Caries (R) in distal aspect of second molar shown as a black patch. Ragged edge (P) to faulty filling has encouraged food stagnation with production of a deep pyorrhœa pocket (Q). Advanced periodontal disease between molars in a patient of good resistance, who has put up a sclerotic barrier in the cancellous tissue of the septum (O).

FIG. VII.—Caries (R) below a filling shown as a dark radiolucent halo. Death and putrefaction of the pulp has led to chronic apical infection (N).

FIG. VIII.,A.—Shows evil following extraction of first permanent molar, viz.:—
(1) Occlusion with the opposing upper molars is thrown out of gear. Therefore loss of natural function and cleansing.
(2) Food impaction between the molars has produced caries (R) and an incipient pocket.
(3) Food stagnation under the tilting side of the crown has produced a deep pyorrhœa pocket (M). Ultimately the tooth will be lost.

FIG. VIII.,B.—Periodontal disease produced or aggravated by subgingival tartar (L) seen as projections on the side of the roots with well-defined pockets below.

PART II.

FIG. IX.—Progressive stages of periodontal disease destroying the alveolar sockets commencing at the margin in the incisor (A, B, C, D), and molar regions (E, F) of the lower jaw. Note the well-defined spurs of bone coming up between the teeth in IX., A, and disappearing in the remaining ones till the last one shows the teeth ready to fall out.

FIG. X.—General enlargement of the periodontal membrane (K) around a devitalised tooth.

FIG. XI.—(A) Shows the earlier stages of generalised thickening of the periodontal membrane (K) without loss of bone and often accompanied by a sclerosis of the lamina dura.
(B) Later stage of the same condition, sclerosis having extended into the neighbouring cancellous tissue, but rarefaction accompanied by the formation of a granulomatous membrane K', and loosening of the tooth has supervened.

FIG. XII.—A crescentic area of rarefaction (J) over the apex of the second premolar. This condition is of periodontal *not* pulpal origin and the tooth is absorbed not foreshortened—cf. Fig. II. It was removed under aseptic conditions, and three ampoules of broth inoculated with the first blood taken in a pipette from the apex of the socket gave a pure growth of *Strep. viridans*. The apex of the tooth also gave a scanty growth of the same organism in pure culture.

FIG. XIII.—Proliferation of cementum (exostosis) due to irritation of the cementoblast cells of the periodontal membrane, giving rise to swollen bulbous roots (I).

or preferably a proper viewing box. The films should be the best procurable. Even when the definition of the radiogram is very fine, imagination must play a large part in visualising the morbid anatomy of the parts seen, and therefore mediocre radiograms are misleading. Only the central portions, where the rays have penetrated the tissues and impinged upon the film with correct incidence, should be used, and the outer portion of a film where the image may be distorted should be discounted. A sufficient number of exposures should be made to make this possible. Twelve of the stock size dental films is, in my opinion, the minimum, supplemented when occasion arises by two more and by stereoscopic films of uncertain areas. The doctor should make it his duty to learn, by watching dental films being taken, the relative positions of tube, tissue, and film for the various groups of teeth in the average mouth.

Examples of the importance of taking several views are illustrated in Fig. I., E, where the shadow of the anterior palatine fossa has been transposed behind the apex of the lateral incisor, giving rise to the appearance of an apical rarefaction; and in Fig. II., where by using too acute an angle of incidence the radiologist has produced an appearance of foreshortening which resembles a type of absorption of the roots of the teeth occurring in one manifestation of dental sepsis. The desideratum is that the shadow of a tooth projected on to the film should appear identical in length with the tooth, but, as the dental film cannot be placed in an ideal radiological position, the factors of human judgment and error cannot be entirely eliminated. Some radiologists tend to foreshorten the images of certain teeth, whilst others tend rather to elongate them.

With the films upon a viewing box in a suitably darkened room a general inspection should be made first to note general characteristics not merely of the teeth themselves, but particularly of the periodontal membranes and of the cancellous tissue of the jaws in this region.

FIG. III., A.

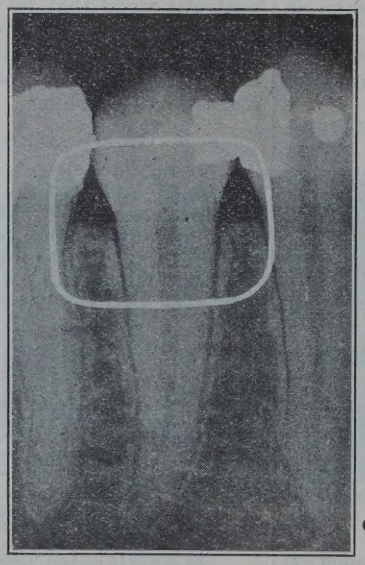

FIG. III., B.

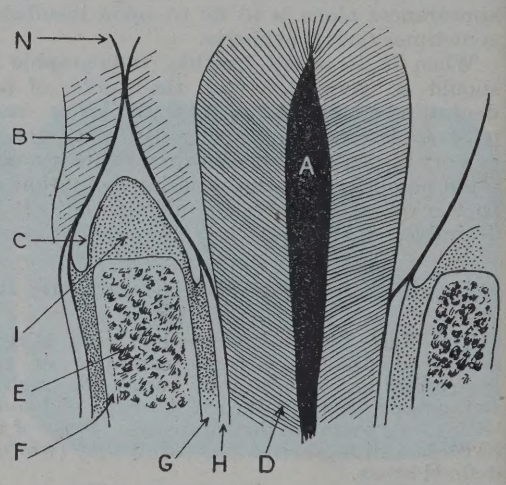

III., A.—Enlarged radiogram of one of the normal premolars shown in Fig. I. A diagram of the framed portion is shown in Fig. III., B.

III., B.—A = Pulp. N = Nasmyth's membrane, an epithelial layer covering enamel (B) and reflected on to gum at the termination of the enamel in the gingival trough. C = Gingival trough lined by epithelium (see Fig. III., C). D = Dentine. I = Interdental papilla not visible in X ray, greatly filling space between the teeth. E = Cancellous bone of interdental septum. F = Lamina dura which appears as white line in X ray and is continuous over top of septum to the next socket. G = Periodontal membrane which appears as black line in X ray. It has strong fibrous bands which sling the tooth in the socket. H = Cementum which secures the ends of the fibrous bundles to the dentine.

A General Survey.

In the general preliminary survey the following points should be noted:—

1. The arrangement of the teeth in relation to the normal position (see Fig. I.). In the normal young adult with a well-developed arch the teeth are arranged vertically in perfect order, the crowns of adjacent ones in contact but not overlapping, and the roots on all of them tapering to finely pointed apices. In length the roots are approximately twice the height of the crowns. When the premaxillary region is underdeveloped (due probably to early adenoids) the arch of the teeth is pinched in this region and malposition and overlapping of the incisor teeth in varying degrees result. Underdevelopment posteriorly causes shortening of the jaws in an antero-posterior direction, when the third molars (or wisdom teeth) of both jaws are unable to erupt easily in a vertical direction and may even remain buried. They are subject to considerable variation of position. Fig. IV. shows one of the typical misplacements, the importance of which is discussed below.

2. The presence of other unerupted teeth, supernumerary teeth, and foreign bodies, and the tilt or evidence of undue stress in teeth adjacent to edentulous spaces or supporting artificial dentures.

3. The character of the osseous framework generally and any gross changes in this tissue such as sclerosis or rarefication.

4. The position of those normal structures both radiolucent and radiopaque, which act as landmarks. Normal structures may be mistaken for pathological conditions, or may be encroached upon by morbid conditions occurring around the roots of the teeth.

STRUCTURES IN THE MAXILLÆ.

The delineation of the *antrum* (Fig. I., B) by a thin layer of hard bone surrounding a radiolucent area above the molar and premolar teeth should be observed. This sinus extends sometimes as far forward as the lateral incisor, and is often mistaken for an area of pathological destruction especially when septa dividing it into loculi are present. Conversely, a small dental cyst invading the antrum may easily be mistaken for a loculus of that sinus. Stereoscopic plates and a comparison of the two sides are helpful in avoiding such errors. A large dental cyst displacing the floor of the antrum upward and filling the entire space formerly occupied by that cavity may also be unrecognised, but with this the physical signs are more apparent.

The *malar process* (Fig. I., A) often casts a radiopaque shadow over the apices of the last upper molar teeth, preventing clear definition. It should not be mistaken for an area of pathological sclerosis.

The tip of the *coronoid process* sometimes appears on an upper molar film.

In the front of the mouth the *median suture*, the *anterior palatine canal, foramen and fossa* (Fig. I., D) may be mistaken for periapical destruction above one or other of the central incisors, especially when the tooth is known to be pulpless.

The *nasal septum* often throws a radiopaque shadow across the roots of the upper incisors, and the *nasal fossæ* are sometimes observed in close relationship to the apical extremities of the central incisors (Fig. I., D).

The *canine fossa* over the lateral incisor and the canine varies greatly in depth, and radiograms of this region show corresponding variation in radiolucence.

STRUCTURES IN THE MANDIBLE.

The *inferior dental canal* is seen extending forward below the roots of the molars and premolars in Fig. I., F. Disease

of these teeth is a frequent source of chronic trouble in this branch of the trigeminal nerve, which may persist indefinitely after the teeth themselves have been removed. It will be noticed that the canal is closer to the third molar than the other teeth, a fact which is of importance in surgical procedures connected with this tooth. Impacted third molars are found not uncommonly grooved, where they were in contact with the nerve.

The *mental foramen* (Fig. I., G) is seen as a radiolucent area between the apices of the first and second premolars. Sometimes it is hardly to be distinguished, but at other times it may appear so closely applied to the root of a premolar as to simulate a morbid condition of this tooth and forms a common pitfall in diagnosis (Fig. V.). If the radiogram is of proper texture determination may be greatly aided by tracing the inferior dental canal to the foramen and by radiograms taken from different angles, coupled with the electric test for vitality of the tooth concerned.

In the region of the lower molar roots and roughly parallel to the mandibular canal, but above it, is a radiopaque band. It is a shadow thrown partly by the *mylohyoid line*, which is lingual to the molar roots, and partly by the dense bone of the *external oblique line*, which passes to the outer side. In strongly built subjects this shadow is sufficiently opaque to obscure the detail of the roots of the last two molar teeth.

Having reviewed these anatomical variations before proceeding to the critical examination, it is wise to look at the radiograms as a whole, noting any change common to them all, such as increased or decreased definition of the roots, increased or decreased thickness of the trabeculæ of the cancellous bone, general loss of the alveolar edges, the presence of any unusual degree of apical rarefaction, or of sclerosis.

Detailed Inspection.

After a general inspection radiograms of the teeth should be examined seriatim with a lens, the observer paying attention to the structures described below and shown in Fig. III., A and B.

1. *The crown.*—The enamel is clearly defined as a cap of denser material covering the exposed portion of the tooth, being thickest in the cusps on the masticating surface and thinning to its termination at the neck of the tooth, where it ends in a delicately chamfered edge (Fig. III., A and B) having no projecting ledge or sudden break. Fillings and artificial crowns should be made to imitate this smooth continuity of surface from root to crown as closely as possible, otherwise stagnation of food occurs at this rough place with injury and infection of the subjacent periodontal membrane, and ultimate caries in the root deep to the filling (Fig. VI.).

Caries beneath a filling may be seen as a radiolucent (dark) area extending even down to the pulp, and is a source of neuralgia and later of infection and death of the pulp (Fig. VII.). The position of the crown relative to its neighbours should also be noted. A slight breach at the point of contact, leading to food impaction, or undue tilting of the crown, interfering with proper cleansing, gives rise to caries (Fig. VIII., A) and to periodontal infection. For the same reason the presence of subgingival tartar should not be overlooked (Fig. VIII., B).

2. *The pulp chamber and canals.*—These should have a regular, clear outline. Secondary dentine—as an inward bulge upon the pulp boundary—or pulp nodules may give rise to neuralgia from a tooth externally normal and clinically alive. This deposition of dentine within the pulp and the much rarer destruction of dentine proceeding from the pulp outward are the only affections of the pulp which are portrayed in a radiogram. It is not possible to distinguish whether a pulp is dead or alive. When the pulp has been extirpated and the root filled with radiopaque material, such as gutta-percha, the apparent mechanical success of the operation should be observed; but a well-filled root does not necessarily mean a sterile, healthy root, for the dentinal tubules may be full of septic material. It is one stage better, however, than a poorly filled pulp chamber or than a pulpless tooth with no root filling at all.

3. The *root of the tooth, the periodontal membrane*, and the *lamina dura* of the socket should be examined together. The *surface of the root* should appear smooth and should pursue a regular course toward the apex. There should be no excrescences or excavations upon it and the apex should be moderately pointed, unless bending of the root toward or away from the rays hides it. As the dentine is denser than the bone, the shadow cast by the root obscures that of the superimposed and subjacent cancellous tissue, except occasionally toward the end of finely tapered roots, where the cancellous network may even interfere slightly with the shadow of the root apex. The *periodontal membrane*, interposed between the tooth and the wall of the socket, appears as a fine, black radiolucent) line, clearly defined and of even thickness, except at the apex of the root, and of almost the same tenuity as a hair. The *lamina dura* of the socket is seen as a thin white (radiopaque) line of compact bone covering the cancellous tissue of the alveolar processes. There should be no breach in its continuity.

4. The *crests* of the interdental septa are formed by the junction of the laminæ duræ of the adjacent sockets where they join that covering the cancellous tissue of the septum. Between the incisor teeth, where the interproximal spaces are narrow, the septal crest appears as a thin, elongated spine of hard bone formed by the convergence of the laminæ duræ of the two socket walls (Fig. I., C). Toward the back of the mouth, owing to the greater convexity of the crowns of the teeth, the interproximal spaces become broader, and here the lamina dura passes straight across from the margin of one socket to that of the next (Fig. I., G).

5. The *cancellous tissue* of the bone between and around the teeth. Its recognition is largely a consideration of the thickness of the trabeculæ, the spaces which they enclose, and their general arrangement. In the maxillæ the pattern is that of a fine, irregular small meshed honeycomb; while in the mandible the trabeculæ form large irregular spaces with a general tendency downward and forward in the premolar and molar region.[1] No definition, however, of normal appearing cancellous tissue can be given and in apparent health it is subject to considerable variation.

PART II.—Periodontal Infection.

THE earliest radiographic sign of infection of the periodontal membrane, either from the gum margin or through the root of the tooth, is a thickening of the dark line of this tissue with an increasing blurring or irregularity both of the definition of the side of the dental root and of lamina dura of the socket wall. This was pointed out by S. Colyer eight years ago.[2]

Where a marginal infection of the ordinary gingival type is taking place, there is to be seen a localised thickening of the periodontal membrane, extending a variable distance down the side of the root towards the apex. This is succeeded by a solution of the lamina dura in those portions of the sockets to be affected earliest—i.e., the marginal interdental crest—and ultimately by the disappearance of the cancellous tissue subjacent to it. Distribution of the lesion in the teeth of the denture is determined by a variety of exciting factors. The disturbance may be localised to one tooth, being produced by a ledge of a faulty filing (Fig. VI.), or by subgingival calculus (Fig. VIII., B), or by an uncleansable area below the convexity of the crown of a tilted molar (Fig. VIII., A), and perhaps aggravated in this case by the trauma of faulty occlusion. Or it may be seen affecting all the teeth to a greater or less degree in the condition of general marginal periodontal disease associated with mouth-breathing or faulty oral hygiene.

Progress of the condition consists in the thickening of the periodontal membrane, preceding resorption of the alveolar bone. Detachment of connective

[2] THE LANCET, 1922, i., 175.

tissue fibres from the affected surface of the root subsequently leads to "pocket" formation. The lymphatic drainage is mainly by the perivascular channels and, since these are mostly axial to the root, it follows that a pyorrhœa pocket tends to elongate towards the apex rather than to encircle the root (Fig. IX.).

The rate of extension of the disease appears to depend upon the local and general resistance of the individual. A periodontal pocket, however, should not be ignored. Under the most favourable conditions neglect of it will ultimately cause the loss of the tooth, an event of minor importance compared with the fact that the pocket acts as a portal, allowing ingress and ultimate entrenchment of infection in the cancellous bone of the jaws. Where a number of teeth are affected the area of absorption of sepsis becomes considerable.

The normal, but unobliterated, dental sulcus, situated behind a partially erupted lower third molar, may become a septic trough, forming a fertile pyorrhœa pocket which should be eliminated (Fig. IV.).

Another type of periodontal disturbance manifests itself as a *general even thickening* of the periodontal membrane. It may be localised to one tooth. In a dead one it is due to sepsis or some other irritating product diffusing through the substance of the root (Fig. X.). When it occurs around the root of a live tooth, this thickening indicates a state of chronic periodontitis, initiated by the trauma of faulty occlusion or some other mechanical force, and is significant of bacterial infection. In its earlier stages the black line of the membrane appears two to three times its normal thickness, with a corresponding thickening of the lamina dura if the resistance of the patient is good (Fig. XI., A); later, however, the membrane may appear 10 or 12 times its normal thickness, its wall of lamina dura has disappeared, and the root, instead of being clearly demarcated, has the appearance of being covered by a fluffy felt glove in contradistinction to a tight kid one (Fig. XI., B). A tooth in this state is invariably infected, and can cause constitutional disturbance. It may give rise to no local symptoms; but on examination it will be slightly loose, and if tapped lightly in an axial direction with the end of a metal instrument, it will give a dull damped note due to the cushioning of the swollen membrane in contrast to the resonant pitch of corresponding healthy teeth. In my experience there is a close correlation of this condition when it affects all the patient's teeth with intestinal toxæmia and with a raised percentage of streptococci in the fæces. In advanced cases a heavy growth of streptococci, usually in pure culture, is always present in the dental sockets. Remedial treatment of the gums and jaws is ineffective and temporary so long as the bowel remains deranged, and becomes a much easier matter and more lasting when the intestinal condition has been cleared up. The percentage counts of intestinal bacteria show an immediate drop in streptococci when the sepsis in the mouth is removed.

How far it is possible to correlate with the two definite types of periodontal lesion just described—namely, the marginal and the general—two other less easily classified disturbances, often to be seen in a set of dental films, is difficult to say. They are: (1) a condition in which an absorption of the root apex takes place, leaving either a crescentic-shaped radiolucent area capping the root in its place (Fig. XII.), or a regeneration of alveolar bone pari passu with the absorption; (2) a proliferative cementosis (due to irritation of the cementoblast cells of the periodontal membrane), giving rise to swollen bulbous roots (Fig. XIII). Proliferating cementosis may be either local round a devitalised tooth or general as a manifestation of periodontal disease.

The generalised periodontitis (previously described), which presents the swollen "fuzzy" membranes is usually not accompanied by a sclerotic reaction in the neighbouring alveolar bone and, since it is associated with ill-health of a toxic type occurring early in adult life, it may properly be regarded as periodontal infection occurring in a patient of poor resistance. In contradistinction, the type with the bulbous roots occurs usually later in life in individuals of robust constitution, and is associated with a sclerosing activity in the bone, which appears whiter than normal with thickened laminæ duræ and trabeculæ. It is seen in "gouty" people, by which adjective these teeth were formerly described. It is also toxic in origin, the only difference being the greater resistance and diminished susceptibility of the patient.

The remaining phases—that of absorption of the apex with concurrent regeneration of the bone and the similar condition, but without regeneration of bone, may be placed between the two main conditions, the former nearer the side of good resistance, and the latter towards that of poor resistance.

This radiological classification forms a useful basis for the computation of the dental sepsis present, and is of assistance in determining the form of treatment most effective in preventing persistence of it residually.

C. BOWDLER HENRY, M.R.C.S., L.D.S. Eng.,
Assistant Dental Surgeon, Royal Dental Hospital of London.

Note.—The first part of this article appeared in THE LANCET of March 1st, where the fine detail of the radiograms was partly lost in reproduction. The third part will appear next week.—ED. L.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JUNE 21ST, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 241 (last week 266); scarlet fever, 1584; diphtheria, 1019; enteric fever, 54; pneumonia, 722; puerperal fever, 48; puerperal pyrexia, 102; cerebro-spinal fever, 13; acute poliomyelitis, 3; encephalitis lethargica, 22; dysentery, 5; ophthalmia neonatorum, 123. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 24th–25th was as follows:—Small-pox, 399 under treatment, 9 under observation (last week 460 and 11 respectively); scarlet fever, 1925; diphtheria, 2030; enteric fever, 20; measles, 549; whooping-cough, 78; puerperal fever, 23 (plus 13 babies); encephalitis lethargica, 122; poliomyelitis, 1; "other diseases," 19. At St. Margaret's Hospital there were 15 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 31 (9) from measles, 6 (3) from scarlet fever, 22 (6) from whooping-cough, 28 (3) from diphtheria, 43 (8) from diarrhœa and enteritis under two years, and 22 (2) from influenza. The figures in parentheses are those for London itself.

Fatal cases of measles were more evenly distributed, Southampton and Birmingham each recording 3. Liverpool reported 7 deaths from diphtheria. Of the 35 deaths from diarrhœa outside London 6 each were reported from Birmingham and Liverpool, 5 from Manchester.

The number of stillbirths notified during the week was 303 (corresponding to a rate of 40 per 1000 births), including 49 in London.

SPECIAL ARTICLES

BIOPSY AS A PRELIMINARY TO RADIUM TREATMENT.

By G. E. Birkett, *M.C.*, M.R.C.S. Eng.,

HONORARY RADIOLOGIST, MANCHESTER AND DISTRICT RADIUM INSTITUTE, AND CHRISTIE HOSPITAL FOR CANCER.

There is a considerable difference of opinion as to whether a biopsy should be performed as a preliminary to radium treatment. At the Fondation Curie the procedure is carried out in every case, and no case is included in the statistical records in which positive evidence of malignancy is not obtained. This is done principally in order to obtain absolute scientific proof that the cases treated were definitely malignant. On the other hand, there are a number of workers in England who consider that it is not in the best interests of the patient for it to be done as a routine in that the removal of a piece of tissue tends to stimulate growth locally, and to bring about metastasis by opening up lymphatic channels and blood-vessels into which odd cells may be implanted by the knife. It has been my lot to have dealt with almost no other cases than those of malignant disease for the past six years. In the earlier years the cases referred to the clinic were hopelessly inoperable or recurrent after operation. A study of these latter cases has convinced me that there is nothing worse in malignant disease than an incomplete operation, and that often increased rapidity of growth and metastasis follow rapidly in its train. Cases which come to mind are those of breast carcinomata, in which only a local amputation has been performed, or in which it is obvious from the length of the scar that the axilla could not possibly have been cleared. It is little short of a tragedy to see some cases which have been treated in this way referred for treatment with extensive local recurrence, diffuse infiltration of the skin flaps, and multiple outlying skin nodules. Occasionally I have seen an early epithelioma of the skin mistaken for an inflammatory lesion and incised, with subsequent rapid local spread. Lastly, I have for a long time been struck by the history given by some patients of the hospital class with carcinoma of the floor of the mouth. First of all a "sore place" was noted, and the removal of teeth advised. After which "it became worse," and surely enough the growth had spread rapidly along the alveolar margin whence the teeth had been removed.

Dr. W. E. Gye [1] in his Lloyd Roberts Lecture referred to the experimental fact that if an implant of Jensen's rat sarcoma in a mouse would not grow, the best thing to do was to incise it. Mr. Geoffrey Keynes also has told me that he has discontinued biopsy in breast carcinoma—a procedure carried out in his first fifty cases when the radium needles were being removed—owing to the fact that in some cases implants occurred in the scar of the skin incision. There was an old adage in connexion with rodent ulcers "Noli me tangere," and I believe in the old days the phrase was synonymous with the condition. Interpreted it would seem to mean that no treatment at all is better than incomplete or inefficient treatment.

Largely for the above reasons I, personally, do not encourage routine biopsy as a preliminary to radium treatment. In order, however, to appreciate the position more fully it is necessary to consider the various common sites of malignant disease, and also to assess the possible harm which may result from an incorrect clinical diagnosis if radium treatment is given.

Buccal Cavity.

If a "lump" is present in the tongue, which is not ulcerated, with or without glandular enlargement, the diagnosis probably rests between gumma, tubercle, or malignant disease. If ulceration exists there is the same problem, whilst small, simple ulcers may occur in addition. The gumma is usually associated with other evidence of syphilis (i.e., a specific glossitis) and a Wassermann reaction can easily be performed. Even so malignant disease commonly is superimposed on a specific glossitis in the anterior third of the dorsum of the tongue, but the clinical differentiation is easy for the experienced observer. Tuberculous disease of the tongue is generally associated with well-marked and active pulmonary tuberculosis. The question naturally arises as to what is the result of radium treatment of a gumma or tuberculous disease in this situation. Commonly we treat an epithelioma of the tongue where there is an associated specific glossitis, and usually the associated leukoplakia disappears temporarily, later to return. No harm is done so far as can be observed. I have no experience of having treated a tuberculous ulcer of the tongue, but lupus vulgaris of the skin has been treated with no ill-effects. After all, radium treatment is a conservative method, and the position of the surgeon who in the past was called upon to do a partial or complete glossectomy for the condition was quite different. It seems to me that in this situation, which is notorious for the rapid spread of carcinoma to lymph glands, this spread being explained to some extent by the continuous state of "unrest" of the organ, biopsy is the last procedure one should adopt in the interest of the patient. It is true that we lose scientific proof that all the cases apparently cured are malignant, but if the clinic is a large one, then the number of patients so treated should outweigh any criticism of inaccuracy of diagnosis, which surely must be rare with experienced observers. Finally, the present method of treatment involves at most clinics a widespread removal of the lymphatic drainage area—a Crile's block dissection. From the material so removed sufficient evidence has already been obtained to confirm the clinical observation that radium can deal adequately with the primary growth in buccal carcinoma. This is not surprising when Regaud states that 65–70 per cent. of cases of lingual and sublingual carcinoma treated at the Fondation Curie showed secondary deposits in the lymphatic glands. On the other hand, the French school recommend biopsy in every case, but apart from the point that the scientific value of their records is obviously increased there seems to be no advantage to the patient in its regular performance.

Prof. G. Roussy [2] mentions the case of a gumma of the tongue diagnosed clinically as an epithelioma, which would have been subjected to a total glossectomy but for a biopsy performed at the instance of another surgeon. This criticism does not apply, of course, in the case of radium, which, as has already been noted, is a conservative method of treatment.

Roussy also describes a case in which the biopsy pointed to a chronic inflammatory condition, probably syphilitic, which was confirmed by the Wassermann

reaction. Happily a subsequent examination drew attention to other features, and a fresh biopsy showed a squamous epithelioma. The author's conclusion is that the case demonstrates the value of repeated biopsy; my own would be that the selection of the correct piece of material for biopsy depended upon the clinical skill of the observer. He also refers to the value of biopsy in the treatment of carcinoma of the mouth and tongue. Sufficient, however, is now known with regard to the histology of epitheliomata here, and the variations in type with site, for the clinician to say with a fair degree of certainty what the type and its relative radio-sensitivity will be. For instance, almost all epitheliomata of the base of the tongue are extremely radio-sensitive, and very advanced primary growths yield dramatic local results, such as are rarely obtained in the anterior part of the buccal cavity. For this reason one need rarely abandon hope here as regards the local result. On the other hand, epitheliomata of the anterior third of the dorsum of the tongue are usually superimposed upon a chronic specific glossitis, and the prognosis should always be to some extent guarded, since the response to radium is not so good as in an uncomplicated case. If the above facts are borne in mind I do not think that a biopsy is likely to improve the treatment of a particular case.

J. L. Roux-Berger and O. Monod [3] think that correct treatment is likely to be delayed without biopsy; in their experience a large number of cases is brought to them much too late for effective treatment to be given. It seems to me that their objections would be answered by the statement which I have often made that "all ulcers of the mouth and tongue which persist for more than a week or two in patients over the age of 30 should be regarded as being potentially malignant and referred for expert opinion."[4]

Carcinoma.

BREAST.

In the introductory remarks, reference has been made to the effect of incomplete operations, and most surgeons are not in favour of biopsy as a preliminary to operative treatment. On the operating table, they may, in a doubtful case, remove the tumour locally, and then incise it, but the tendency is to proceed to a radical amputation if doubt exists. Very few will actually excise a wedge for histological examination.

As regards radium treatment, there is as yet only a small number of surgeons who advocate radium treatment in early cases, and in those patients who are usually referred for this purpose the stage of the disease is such that the diagnosis is practically certain. If early cases are treated in the future there is, of necessity, bound to be a small percentage of error in diagnosis. There should be no complications and no mortality following incorrect diagnosis and treatment.

CERVIX UTERI.

In most cases clinical diagnosis is easy. Occasionally the cervix is hard and nodular, usually as the result of multiple tears and subsequent irregular cicatricial contraction, whilst there may be slight bleeding on examination from the presence of erosions. When, however, these patients are examined under an anæsthetic their true nature becomes obvious, and the removal of a piece of the cervix does not settle the matter. Indeed here is a fallacy common to all biopsies, for the information provided depends upon the clinical skill of the operator in removing the correct piece of tissue. In other words, a negative finding does not prove that carcinoma is not present except in the section examined. This is well illustrated in the following opinions collected by Dr. J. Lane Claypon.[5]

Jung (1909) reports two deaths from peritonitis and pneumonia after vaginal disinfection of the growth and before the intended subsequent operation. Death was traced to disturbance of the growth. Risley and Leland (1917) refrain from removing a piece of tissue because of the real danger of dissemination of the disease. Döderlein (1922) regards biopsy as dangerous. Bowing (Mayo Clinic) (1923) says that biopsy, if done at all, should be made just before the second radium treatment, but even so is not without danger. Heymann (Stockholm) (1924) considers that the results with radium have improved in his clinic since the practice of taking tissue for microscopical examination has ceased. Heynemann (1921) says that there are two dangers in biopsy: (1) that the cancer is missed by incomplete examination of the tissue removed, and (2) that infection arises. He lost two early cases by peritonitis after biopsy. Ochsner (1924) says: "I have been impressed with the fact that there is a marked difference in the prognosis in cases in which a portion of the cancer has been cut out for microscopic examination, and those in which the tumour has not been disturbed. The former have invariably died of metastases, even in cases in which the cancer was not in an advanced condition at the time of operation, while in the latter cases we have seen nearly permanent recoveries especially since the introduction of radium and X ray treatment." He adds that he thinks the experienced surgeon should be able to make a diagnosis without removing a piece of the growth. Kupferberg (1925) says that a biopsy or any manipulation of the growth should never be undertaken. Better take the risk of a wrong diagnosis. Dyroff (1925), dealing with the Erlangen material, says that a biopsy is less dangerous after the first ray treatment but that the clinical diagnosis as to recurrence is more accurate than the histological.

RECTUM.

There is considerable divergence of opinion with regard to the suitability of carcinoma of the rectum for radium treatment. Regaud holds the view that the adeno-carcinoma of the rectum is not radio-sensitive, and that such good results as have been obtained are due to excessive irradiation which has luckily been limited in its effects to the malignant tissue. On the other hand, Sir Charles Gordon-Watson [6] considers that the bad results in the past are due partly to poorness of access, and has developed treatment on these lines. His views on biopsy are as follows: "Whenever considered desirable a portion of growth is removed for section. In the earlier cases this was done at the time of the colostomy operation by means of a special punch. In later cases a portion has been removed at the same time as the needles. By the latter method there is less likelihood of stimulating metastasis. When early growths have been dealt with, it has been considered inadvisable to disturb the growth for the purpose of biopsy."

All observers are, however, agreed that carcinoma of the anal canal, a squamous epithelioma, is radio-sensitive and suitable for radium treatment. In growths which start at or near the anal margin a clinical diagnosis will usually suffice, but there will arise the case in which it is difficult to decide clinically whether the tumour has arisen from the rectum or anal canal. It seems, therefore, that in such cases a biopsy must be taken to decide whether one is dealing with an adeno-carcinoma or a squamous epithelioma, since excision is usually regarded at present as the method of choice in operable cases of rectal carcinoma.

BLADDER.

In bladder carcinoma the danger of implanting growths by manipulation and trauma is well recognised by urologists. A suprapubic cystostomy has usually to be performed for the insertion of radium, and the advantages of inserting radium at the same time rather than to have to wait for a positive diagnosis

from a microscopical section and to reopen the bladder are obvious.

In all the above situations, with the exception of certain cases of carcinoma of the rectum, there would seem to be but little advantage to the patient, and certainly no disadvantage in not performing a biopsy. The main objection is the lack of scientific proof; but this surely need not be necessary if results from large numbers of cases are considered, in which the error in diagnosis should be very small.

Other Tumours.

There is, however, a large group of tumours in which clinical diagnosis is difficult, and for which one cannot possibly lay down general rules. As a class one might refer to them as subcutaneous tumours. When they occur in areas known to contain lymphatic glands, as in the neck, axilla, or groin, a primary tumour elsewhere must be eliminated by careful examination. When this has been done the problem is infinitely more complex than that of any of the main situations which have previously been discussed. In the neck tubercle, Hodgkin's disease, lymphatic leukæmia, branchial carcinoma, secondary glands from a mediastinal tumour, or a carcinoma of the stomach all suggest themselves, as well as primary sarcomata of various types. Even the advocates of biopsy are against this procedure in the rapidly growing sarcomata at any rate, holding dissemination to be a real danger. If a rapidly growing tumour occurs in these situations probably the safest procedure is some form of external irradiation such as radium at a distance or deep X rays without a biopsy. In slowly growing tumours a biopsy is, one considers, necessary in order to determine the correct line of treatment. A branchial carcinoma would be treated by interstitial irradiation, a fibro-sarcoma by combined excision and interstitial irradiation, Hodgkin's disease by X rays—to give examples of the importance of a correct diagnosis. (The same line of argument is applicable to subcutaneous tumours elsewhere.)

Finally, there remains for consideration the importance of a correct diagnosis in situations in which the complications of radium treatment may be such that it would only be undertaken if no other method of treatment were suitable. Tumours of the nose and accessory sinuses are cases in point. The complications of bony necrosis following radium treatment are serious and distressing, and treatment should not be undertaken lightly. Biopsy is for these reasons preferable. Carcinoma of the larynx falls into the same category.

Healing after Biopsy.

I have recently received the following statement in connexion with biopsy before radium treatment. "Some surgeons refuse to do a biopsy because they have found that healing is much retarded by the application of radium before the biopsy wound is completely healed, and on the other hand they do not think it justifiable to delay applying the radium until time has elapsed for complete healing to take place." It is difficult for me to criticise this statement on account of my personal attitude and practice with regard to biopsy. It would be quite easy to use the statement as an additional argument against its performance, but one does not feel justified in doing so for many reasons. In the first instance one should examine the usual result of radium treatment in certain ulcerative lesions, such as carcinoma of the tongue, epithelioma of the skin, and rodent ulcer. If surgical excision were performed in any of these conditions without any attempt being made to bring the edges of the wound into apposition, would healing occur more rapidly than it does after radium treatment? I do not think it would. Secondly, one should consider the healing of wounds which follows the insertion of radium by open operation. The operation may be a standardised one such as a radical amputation of the breast or a Crile's block dissection of the neck, and radium is used as an adjunct to surgical procedure. An increase in the normal tissue exudate is noted, but so long as good drainage is provided healing is not retarded. On the other hand, the operation may be for the purpose of providing good access for the insertion of radium, and probably the best example to take is that for the insertion of radium into the lymphatic drainage area in the neck in a case which is considered unsuitable for a block dissection. Skin-flaps are reflected in the same way and the sternomastoid muscle divided and reflected upwards. After the common carotid and internal jugular have been defined a large number of needles (30 to 40) are inserted into the area and the wound closed. The wound must be reopened in seven or eight days for the removal of the radium, and patients so treated are usually discharged six days later. Another common example of the combined use of radium and surgery is the mixed tumour of the parotid gland. They vary in radio-sensitivity and tend to recur locally. Commonly they are treated in Manchester by enucleation and the insertion of six to eight needles in the wound for two to three days. I feel sure that the surgeons who like this to be done would reconsider the position if healing were delayed and an unsightly scar the result.

ROYAL SANITARY INSTITUTE.

CONGRESS AT MARGATE, JUNE 21ST–28TH, 1930.

ABOUT 1600 delegates, members of the Institute and overseas visitors, including a large contingent from the American Public Health Association, attended this congress. In his presidential address Lord CORNWALLIS drew upon his long experience as chairman of the Kent County Council. He touched on the incomplete solution of the housing problem and its effect on agricultural labourers, and advocated the derating of small cottage property. In referring to the sanatorium deadlock, he hoped that the good work of the British Legion at Preston Hall Colony would be widely imitated. He anticipated much progress in schemes to benefit child life as the result of the establishment of the larger health unit. He looked forward to an increase in the number of voluntary health workers, and eulogised the work of such bodies as the rural community councils of Kent and Oxfordshire. The county of Kent was, he said, being urbanised in the neighbourhood of London, industrialised by recent colliery schemes, while it suffered like other parts of the country from the bungalow disease. Regional planning was urgently necessary, and a good beginning had been made in East Kent.

The congress then divided into six sections at which over 60 papers and addresses were submitted,

many of them coloured by the impending changes in local government.

Imperial Responsibilities in Hygiene.

Presiding over the Section of Preventive Medicine, Sir ANDREW BALFOUR (whose address was read in his absence by Prof. JAMESON) said that England had been termed the cradle of modern hygiene, but he was afraid that visitors from overseas might get shocks on seeing the litter in the streets and the primitive scavenging arrangements in London and some of our great cities. Compared with the Dutch we were rather an untidy and not a very cleanly people, and until sanitary education had reached a higher plane we could not set an example to others. We had, however, recently risen to our graver responsibilities in promoting the health of our tropical possessions and smaller colonies, and a remarkable change had taken place in the way the medical and sanitary needs of native populations were viewed by the Colonial Office. The study of tropical hygiene had reacted on home hygiene and had drawn attention to insect nuisances in these islands. The outlook of the teachers of the future must be widened and the student of hygiene familiarised with some features of parasitology in the tropics. The Institute, he said, had realised its responsibilities in the training of sanitary inspectors for work overseas.

Dr. M. Z. SHAFEI, representing the Public Health Department of Egypt, spoke warmly of the services Sir Andrew had rendered to public health in Egypt.

Education of Health Personnel.

THE MEDICAL STUDENT.

Dr. G. F. BUCHAN (Willesden) dealt with the education of medical students, most of whom were, he said, destined for general practice. They must have specialists as teachers, but from interest in his own specialty the specialist was apt to forget the medical students' probable future, and in consequence the resolution adopted by the General Medical Council in 1923 as to the preventive outlook was ignored. There were exceptions. Bacteriology had always been treated in relation to prevention. More recently obstetrics and pædiatrics had assumed a preventive character, and surgery was following suit. Medicine, however, stood where it did. The school medical service came into being in 1907, and a generation was growing up accustomed to medical supervision. Before long, he thought, medical supervision would be applied to the adult, and the slogan of the New York Health Department, "Go to your doctor before he has to come to you," would be translated into some practical form of preventive medicine in this country. Some 30 years ago, when he was a medical student, he learned how disease had developed from the normal, but it was never suggested that at some stage of the process it might have been possible to arrest its course. In teaching, the demonstration of the grosser lesions of an incurable disease had always been more popular, because more spectacular, than the demonstration of the obscure symptoms of an incipient and curable condition. When school medical inspection began it was thought to be a job suitable for a young man fresh from hospital. It was now realised that the detection of the early beginnings of disease was difficult for an experienced practitioner. In his opinion the future of the health of the race, as well as the future of the medical profession, lay in regular medical examination and supervision. The medical student must have better facilities for the study of the normal. The medical graduate, as things were, might be turned out capable of discussing diets for diseases of altered metabolism, but unable to prescribe a suitable dietary for the maintenance of the health of a poor family.

THE POST-GRADUATE.

Prof. W. W. JAMESON (London School of Hygiene) said the D.P.H. curriculum had changed much since it was instituted. He thought candidates should have some experience of practice before beginning such a specialised course of study, but he would like to hear opinions as to the G.M.C. rule that two post-graduate years must elapse before taking the diploma. At the London School they had instituted a part-time course which lasted one year, which included the 280 hours for the Part I. laboratory work in chemistry and bacteriology. They had also added applied physiology, which he considered of the highest importance and the basis of personal hygiene. Ventilation, lighting, and heating were best dealt with in a course of applied physiology, also nutrition, assessment of physical fitness, and industrial hygiene. They believed that they had successfully coördinated the laboratory work with the work of Part II. It was difficult to find a single public health unit where all the practical training in public health administration under a medical officer of health could be obtained, and they had met this difficulty, he believed successfully, by arranging for many special demonstrations under several health authorities and at many institutions. Their 12 months' course was part time, and he would much like to be able to establish a 9 months' full-time course which would fit in with the one year's leave of absence of the colonial medical service, and he hoped to get the consent of the G.M.C. to this modification. Anyone who took up post-graduate teaching undertook a serious responsibility, as this post-graduate work claimed the very best from the teacher. He was much in favour of short refresher courses for the senior medical members of the public health service. A great post-graduate clinical school was now being established for London. Why not have one also for the public health service?

Dr. A. S. M. MACGREGOR (Glasgow) said that the teaching hospitals admitted far too many advanced cases. He thought we should obtain the preventive outlook among practitioners more easily when the insurance system had been extended to dependants. As the medical officer of health was only to be an interpreter of results, the laboratory work in the D.P.H. curriculum might be cut down.

Colonel P. H. HENDERSON (War Office) approved Prof. Jameson's suggestion for a shortened course which would be suitable for army candidates.

Dr. E. H. CULVER (South Africa) said they had largely adopted home ideas for the curricula at their two universities, modified to meet local needs as to parasitology, &c. As a lecturer in physiology he had seen to it that applied physiology had a proper place in the Johannesburg course. In a new country they had not to fight old traditions, and thus Sir Leonard Hill's teaching was more in evidence in Johannesburg than at home, and the kata-thermometer was in use in their theatres. They also had useful fortnightly refresher courses for practitioners.

Surgeon-Commander G. H. HAYES, R.N., said the naval service was essentially preventive, and they also found the kata-thermometer useful.

Dr. W. BUTLER (L.C.C.) considered laboratory work very important for teaching accuracy, and thought they should be careful about making changes in the curriculum.

Dr. W. G. SAVAGE (Somerset) thought graduates might begin their curriculum for the D.P.H. immediately after qualifying, and that laboratory work was very important in keeping the scientific aspect in the forefront. Applied physiology should certainly be added to the curriculum. The 1923 G.M.C. resolution as to the preventive aspect was not being acted upon, and the Council must be pressed to make effective what was at present only a pious aspiration.

Prof. HAROLD KERR said the preventive aspect had permeated the Durham curriculum. He thought the public health courses for the medical student might be made more interesting.

Dr. F. MIRANDA said the work of Mackenzie was highly esteemed in Mexico, and the doctrine that it was too late to try to cure diseases when anatomical changes had taken place. The curriculum at Mexico University included both physiology and physiological pathology. They endeavoured to lay stress, not on the name of the disease, but on the nature of the deviation from the normal.

Prof. A. BOSTOCK HILL (Birmingham) said no mention had been made of propaganda, and pointed out that the public were being gra ually weaned from the bottle of medicine to the preventive outlook, thus preparing the way for periodical medical examinations.

Prof. JAMESON, in replying, again emphasised the importance of applied physiology. He also mentioned that the teachers of physiology had succeeded in having it recognised as a pure science, thus perhaps increasing the difficulty in securing a teacher for applied physiology.

TRAINING FOR THE TROPICS.

Dr. ARTHUR E. HORN (Colonial Office) put forward a convincing case for the special training of the staff, who were to work in the tropics, and deal with such diseases as malaria, yellow fever, filariasis, and schistosomiasis. A knowledge of insectology and parasitology was essential. For example, every kind of anopheline mosquito was not equally effective as a vector of malaria. In one district in Malaya, where there was a high incidence of malaria among the coolies, *Anopheles umbrosus* was incriminated—a type which lays its eggs in water thickly covered by bush. The bush was cleared away and *umbrosus* with it, but unfortunately the much more deadly *maculatus* flourished in the now bright sunny waters, and the last state of this place was worse than the first until the bush was allowed to grow again and the waters were dealt with by other means. A staff is thus required who are able to make use of the expensive lessons learned by experience. There is also much further research to do. We have more to learn about the conditions under which mosquitoes become dangerous to man. The precise cause of yellow fever is not yet known, or if a man can contract the disease by other means than the bite of an infected mosquito. No serious attempt has yet been made to eliminate the mosquitoes which convey filariasis and its occasional sequel elephantiasis. Dr. Horn went on to refer to the methods of dealing with the devastating epidemics of sleeping sickness and with ankylostomiasis, and concluded that there was at the present "great need for the study of all branches of parasitology and less demand for the finer aspects of chemical and physical analysis; a wider field for the employment of simple sanitary devices and less opportunity of employing more complicated engineering schemes."

SANITARY INSPECTORS.

Mr. H. T. PERRY (chief sanitary inspector, Kingston-on-Thames) outlined a suitable course of training for sanitary inspectors. He visualised a student leaving the county school at the age of 17 after passing a matriculation examination and spending four years in going through the routine of a health office, first as clerk and then as assistant inspector, and throughout the whole period going through a complete course in building construction and other subjects at a technical school, and sitting for his qualifying examination at the age of 21.

Mr. H. CLAY (lecturer in domestic sanitary engineering, London School of Hygiene) thought the present scheme of training was good, and that numbers of suitable young men were being turned out by the technical colleges annually who, after a period of pupilage in a health office, would make efficient inspectors. It would be an advantage if scholarships were available as in Willesden.

HEALTH VISITORS.

Miss A. A. HARRISON dealt with the training of health visitors and the changes in their work and qualifications during the last 25 years. Beginning with the same certificate of the sanitary institute as that held by men, the qualifications of trained nurse and certified midwife had been added and health certificates issued by many bodies, ending with the attempt to establish uniformity by the Ministry of Health.

Mrs. C. B. S. HODSON (Eugenics Society) advocated instruction in eugenics for health visitors, seeing that the health visitors from their knowledge of the families were in an ideal position for giving advice in suitable cases on birth control. During the discussion,

Dr. J. J. BUCHAN (Bradford) mentioned that there was a great dearth of health visitors at the present time. He was not satisfied that they had reached finality in their methods of selection. He did not think it was possible to find out the suitability of a woman for this work by any examination.

Dr. J. A. FAIRER (Leicestershire) said that up to now they had had no difficulty in obtaining health visitors as long as they paid a proper salary, but they had experienced difficulty and lost good workers when the county council in a fit of economy reduced the salaries from £180 to £150.

EPSOM COLLEGE.

THE seventy-seventh annual general meeting of the governors of Epsom College was held on June 27th, at 49, Bedford-square, when the chairman of the council, Dr. Raymond Crawfurd, presided. The scrutineers, Sir William Hale-White, Mr. W. Cyril Tomlinson, and Dr. Septimus Sunderland, reported the successful candidates as under:—

PENSIONERSHIPS.

	Votes.
*Nicholson, Mrs. Agnes A.	6987
†Cadman, Dr. Ernest S. R.	6137
†Greenwood, Mrs. Marie M.	4471
†Humphreys, Dr. Edward A.	4334

* Brodie Sewell Pensioner. † Ordinary Pensioners.

FOUNDATION SCHOLARSHIPS.

	Votes.
Taylor, David H.	15,941
Daw, Ian Almeric	11,509
White, John H. B.	10,389
Butler, Gerald A.	9,409

The secretary reported that Dr. Edward W. Forster, who was at the head of the list of unsuccessful candidates, would be appointed an ordinary pensioner

under By-law 16 at the council meeting which would be held immediately after the annual general meeting, a vacancy having arisen.

Dr. Crawfurd, in submitting the report of the council to the governors, spoke briefly of the progress of the school and the position of the medical foundation. While the annual subscriptions were slightly less, the difference could be regarded, he said, as an accident; there was a moderate surplus on the income and expenditure account, and the numbers in the school had gone up. The general story was one of progress. He alluded to the loss which the school had sustained by the death of Lord Rosebery, who was president for 29 years, and took a practical interest in its activities. In obtaining the consent of Lord Burnham to succeed Lord Rosebery he considered that the governors were to be congratulated.

The following were elected vice-presidents of the College, in recognition of valuable services rendered: Lord Dawson of Penn, Sir Milsom Rees, and Mr. T. Hollis Walker, K.C.

A cordial vote of thanks to the chairman concluded the business.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

THE LÜBECK DISASTER.

THE number of deaths at Lübeck has increased to 46, and 68 children are still gravely ill. As is often the case in this country, the sad event has become a political question. The opposition in the Lübeck Parliament moved that the men responsible for the accident should be dismissed for negligence. The motion was adjourned until the case has been fully elucidated, but criminal proceedings for bodily injury by neglect have now been instituted against the medical director of the Lübeck Health Office, and the chief physicians of the State Hospital and the Children's Hospital. The Lübeck Senate has announced that it will bear the expenses of the treatment of the infants both in hospital and at home. Prof. Calmette, in a letter to a Berlin daily paper, says that such an accident as the one at Lübeck has never occurred with B C G, and that obviously, by a regrettable mistake, the infants received virulent tubercle bacilli. Speaking at the Berlin Medical Society, Prof. Lange discussed the theoretical basis of the Calmette method without mentioning the Lübeck disaster, and stated that numerous experiments on animals and observation on patients have proved the method innocuous. Medical men were thus justified, he says, in trying its immunising action with the necessary precautions.

ZEILEIS *v.* LAZARUS.

The action of Zeileis against Prof. Lazarus, mentioned in my letter of April 5th, was recently tried before a court in Berlin. The action was originally brought to prohibit Prof. Lazarus from stating that the Zeileis method was a humbug and obnoxious, but lately the plaintiff, obviously fearing that the defendant would be in a position to corroborate his statement, only demanded an injunction to restrain him from pretending that he had studied the method at Gallspach. At the hearing Prof. Lazarus gave evidence that he had not been allowed to enter the consultation room in Gallspach, but that he had interviewed there the constructor of the apparatus, an electrical engineer, who had explained to him the technical arrangements; he had also consulted, as an alleged patient, two medical men in Munich who used the Zeileis apparatus. Showing a Zeileis tube to the court he broke it, saying that he would make an end of that humbug. The court gave judgment for the defendant, stating that Prof. Lazarus had rightly declared that he had studied the external features of the procedure in Gallspach, that he had ascertained the nature of the apparatus in Zeileis's residence, that he had become acquainted with the therapeutic methods by consulting disciples of the master, and that being a specialist in radiotherapy he was thus in a position to give an opinion on Zeileis's claims.

ABORTION IN RUSSIA.

Dr. Karlin, of Leningrad, reports in the *Archiv für Frauenkunde* on the results of legalising artificial abortion in Russia. He states that in the larger cities, where abortion is now performed in hospitals exclusively, deaths are no longer recorded, and pathological sequelæ have been reduced to a small number. In the country, however, where women, owing to their great distance from an authorised hospital, continue to apply to professional abortionists, deaths and disease are still common. Since December, 1928, a second abortion has been allowed only nine months after the first abortion. The method used is curettage with subsequent irrigation. Perforation has become unusual, and if it happens its danger is much reduced, because a laparotomy can be performed at once and the woman, being already in the hospital, is not endangered by transport. Poverty is not the only motive for women desiring to abort; there are other motives, such as the desire to be socially independent, or to give the children a better education. Some are afraid of parturition, and of the strain of bringing up children. A few only desire the operation because they are ashamed of being pregnant without being married. Although the immediate danger to life and to health has become comparatively small, Karlin is of opinion that the indiscriminate production of miscarriage must be combated, because of its later sequels. Among these are a prolongation of the first and second stage of labour in later deliveries, defects of the placenta, and deficient involution of the uterus. Amenorrhœa and neuroses are especially frequent in women who have undergone artificial abortion without a previous normal birth. The medical man should, however, consider social indications, such as poverty, numerous previous children, and divorce from the father, as well as medical indications.

The legality of operative abortion is much discussed in Germany, where a reform of criminal law is now in preparation. The matter is treated not only in books, in public meetings, in lectures, but also in plays. Hitherto, abortion has been allowed for medical reasons only, and women desiring to abort for other reasons apply for clandestine operations to professional abortionists, death being a common sequel. Owing to the danger incurred these abortionists charge highly. The mother herself, if denounced, is prosecuted also, and her life is often ruined. The Deutsche Ärztetag, notwithstanding those nuisances, has at one of its last meetings petitioned that artificial abortion, if not performed for medical reasons, should be punished by the forthcoming criminal law. On the other hand, the Berlin association of medical women urges that artificial abortion, if performed by a qualified medical man or woman for social reasons, should be legal. The Criminal Reform Bill is still in the stage of committee discussion in the Reichstag.

ALTITUDE AND HEART DISEASE.

In a paper read before the Berlin Medical Society on the influence of altitude on the circulation, Dr

Aron said that on theoretical grounds it had been thought wrong to send cases of heart disease and hyperpiesis to high altitudes. Nevertheless, patients of this kind often feel very well at high levels. They must, of course, be cautious and abstain from over-exertion, especially climbing. Moreover, those with poor compensation and with progressive arterio-sclerosis must not be sent there, since a certain reserve of cardiac strength is indispensable. Concerning the blood pressure, Dr. Aron said that some authorities have found an increase, some a decrease, and some no effect at all. The advantage of the mountain climate lies in the dryness of the air, which leads to a certain amount of desiccation of the body, and thus relieves the heart and kidneys. Hæmorrhage in the eye, the nose, and the lungs occurs at very high altitudes and under experimental conditions, but never at the heights at which the mountain health resorts are situated. It has been observed that patients with Graves's disease feel especially well in high altitudes, notwithstanding the disorders of cardiac function associated with that disease. Dr. Aron reported experiments made in a low pressure chamber where the pressure was reduced by a quarter of an atmosphere, being equal to an altitude of 2000 metres. His observations supported the opinions already set out.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

HOSPITALS AND SWEEPSTAKES.

AT the meeting of the Diocesan Synods of Dublin, Glendalough, and Kildare, held last week, the Archbishop of Dublin declared his intention of refusing his support, or the granting of any facilities as far as he personally was concerned, to the Dublin Hospital Sunday Fund, if it gave any grant to hospitals which availed themselves of the powers recently given by the Act permitting sweepstakes in aid of hospitals. The Fund, which is mainly made up of church offertories, has hitherto received considerable support from the churches of the diocese. It is to be feared that if the churches fail to support the Fund in which they have been interested they are likely to lose touch with the hospital charities altogether. The difficult problem of the hospitals is not likely to be helped by the Archbishop's intervention.

AN ACTION FOR DAMAGES.

In the High Court, Dublin, last week, before Mr. Justice Sullivan, a case was heard in which Mr. Patrick Moore claimed damages against Dr. Michael Walsh, of Dublin, for alleged negligence on May 6th, 1927, in certifying that the plaintiff was a dangerous lunatic. Without leaving the box, the jury found that there was no negligence, and judgment was entered for the defendant. It appeared from the evidence that in May, 1927, the plaintiff heard wireless messages warning him that he was pursued by assassins. He fled to Kingstown Harbour to seek the protection of a British warship and went on board the Irish light steamer *Irene*. He was there arrested by the police, and he attempted to escape by jumping out of a boat. The magistrate, before whom he was brought, ordered Dr. Walsh to examine him and report on his condition. Dr. Walsh certified him as a dangerous lunatic, and he was detained first in the Grangegorman Mental Hospital, and later, by order of the Chief Justice, in a private mental hospital at Glasnevin. The superintendents of these two institutions gave evidence that at the time the plaintiff was under their care he was suffering from delusional insanity. The same plaintiff had some months ago initiated proceedings against these two gentlemen, but the actions had been stayed by the courts as vexatious.

THE IRISH MEDICAL ASSOCIATION.

The annual meeting of the Irish Medical Association was held in Dublin on June 25th, with Mr. P. E. Hayden, the President, in the chair. The annual report showed that the membership of the Association on Dec. 31st, 1929, was 388. This was less by 21 than in the previous year.

THE LATE DR. HOUSTON.

Dr. John Carson Houston died in Belfast on June 27th after a short illness following operation for gall-stones. He was educated at the Royal Belfast Academical Institution and the Queen's University of Belfast where he won a reputation as a redoubtable Rugby football player. Qualifying in 1909 at the last examinations held by the Royal University of Ireland he took up house appointments at the Royal Victoria Hospital, and later at Belfast City Fever Hospital. During the war he served for several years in France with a commission in the Royal Army Medical Corps. Afterwards entering practice in the north end of Belfast he built up a large connexion, and his professional knowledge and sound judgment inspired confidence in his patients. Outside his work he was a keen geologist and had a remarkable knowledge of English poetry. Silent and reserved among strangers, among intimates he was full of quaint humour and mature thought. He occupied a high position in the esteem of his colleagues, and will be remembered as a kind and skilful physician and staunch friend. He died unmarried.

APPLIED PHYSICS.

ANNUAL INSPECTION OF THE NATIONAL PHYSICAL LABORATORY AT TEDDINGTON.

THE annual inspection of the National Physical Laboratory by the General Board took place last Friday, June 27th, when Sir Ernest Rutherford, chairman of the Board, and Sir Richard Glazebrook, chairman of the executive committee, welcomed more than a thousand visitors. During the afternoon various experiments and pieces of apparatus were on view, a total of over seven hundred exhibits, and choice was difficult. The fascination of delicate instruments of precision, the excitement of a train of experimental difficulties overcome by sheer ingenuity, the marvel of such large-scale working as was seen in the wind tunnels and in the colossal equipment of the high-voltage building, the simple delight of a ride along the water tank—all followed in rapid succession, as the visitor passed from building to building. The demonstrations may be divided into five overlapping groups.

In the section of *Standards* measures of all kinds were shown, from those of weight and distance to precision electrical resistances. These ranged up to 10,000 ohm, and were constructed of two materials of opposing temperature coefficients to make them independent of thermal variations. Methods for the

comparison of standards and for the estimation of characteristic coefficients included those for the determination of international standard freezing-points at high temperatures by means of a valve-controlled vacuum furnace and for the measurement of X ray intensities in terms of the new international unit. The methods used for the rating of instruments of common use, such as watches and clocks, thermometers, telescopes, and speedometers were also on view.

In the section of *Materials* the relationship between the macro-and micro-structure of cast alloys were demonstrated. The methods used for the manufacture and for the study of the constitution of alloys of iron-manganese and iron-chromium could be seen and also the electrolytic preparation of pure beryllium. The examination of the behaviour of mild steel under bending tests in various media with its application to the cracking of boiler plates, the investigation of the mechanism of "creep" in metals under prolonged loading at elevated temperatures, and the research on chains and hooks, all provided examples of the direct application of these studies. These applications were carried further into the fatigue tests on crystals of silver, antimony and zinc, corrosion fatigue tests in vacuo, and high speed fatigue tests on spring plates under reversals of bending strain. The examination of electrical insulating materials under high voltage tests, of X ray protective materials and their efficiency, and of leakage from radium tubes were to be seen in operation.

In the section of *Experimental Methods* were some recently devised laboratory tricks for special purposes. The shadow of smoke from titanium tetrachloride was thrown on a screen to render visible various types of fluid motion. Water was pumped through a glass tank past fixed obstacles of known shape, and the consequent eddies and main lines of flow were thus thrown into sharp relief. This is of use in determining the nature of the wake left behind moving bodies, whether in air or in water, and is being applied to problems of aeroplane design. A very pretty method of detecting flaws and surface cracks in metals, too fine to be otherwise seen, was demonstrated in the metallurgy building. A suspension of fine iron particles in paraffin is poured over the metal while this lies in a strong magnetic field; the intensification of the field in the neighbourhood of cracks and flaws leads to the local deposition of the particles which etch-in these defects in a remarkably clear way. The two shops for the construction of model aeroplane parts and of ships models respectively were full of delightful workmanship. The joinery and lathe work in the former were of a very high order, and in the latter the cutting of model hulls from wax and the making of model aluminium propellors, both carried out automatically to any predetermined form, attracted much attention.

In the section of *Machinery Testing* several pieces of work were being carried out for the Ministry of Transport. An experimental trailer for the determination of tractive resistance and wheel impact, vibration recorders, and remote recording accelerometers were to be seen, some of them in use. Elsewhere the testing of rear reflectors for bicycles and the brightness-difference-threshold meter for estimating glare had direct reference to road vehicle lighting. The acoustics of buildings came under examination in Bushy House. Here the application of sound-pulse photography, a three dimensional model of an auditorium and a ripple tank for the two dimensional investigation of acoustic reflections were to be seen. The lighting of buildings, in respect of the efficiency of light wells, was being investigated, and the ten-foot sphere for the examination of lighting fittings was shown. Outside the high voltage building a spectacular demonstration of flash-over tests on porcelain insulators under artificial rain was made; with a series of vast sparks and artificial thunder-claps it was shown that the effective value of these particular insulators was lowered by 10 per cent. in rain.

In the section of *Design* come the two pieces of large scale research into aeroplane and ship hull design. In the duplex wind tunnel a model was being used to determine the best position on an aeroplane wing for an engine nacelle; beneath the tunnel was shown a complete model aeroplane suspended from a series of electrical balances for the measurement of yawing and rolling movements. In the William Froude national tank a model of an ocean cargo boat which has been for some time working across the Atlantic was under test. It was propelled by its own screw, driven by an inboard motor of $\frac{1}{2}$–$\frac{3}{4}$ h.p., at a speed of eight knots along a 500-ft. tank, through a series of three-inch waves. This represented to scale the conditions met with in a North Atlantic crossing, and was used to determine the propellor efficiency and speed-keeping qualities of ships in rough weather. This tank has proved too short for tests of sufficient duration, and the plans of a proposed new tank lay-out with a length of 700 feet were shown.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

The following appointments are notified: Surg. Lt.-Comdrs. T. C. H. Neil to *Pembroke*, for R.N. Barracks, Chatham; W. Flynn to *Sutton*; J. F. H. Gaussen to R.N. Hospital, Portland; and T. Madill to H.M.H.S. *Maine*.

Surg. Lt. W. A. Hopkins to *Egmont*, for H.M. Dockyard, Malta.

ROYAL NAVAL VOLUNTEER RESERVE.

The following appointments are notified: Surg. Lt.-Comdr. T. W. Drummond to *Victory*; Proby. Surg. Lts. J. J. Dwyer and G. M. Tanner to *Victory*, for R.N. Hospital, Haslar; Proby. Surg. Sub-Lts. R. H. Berry and S. C. Suggit to *Victory*, for R.N. Hospital, Haslar.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. and Bt. Col. (temp. Col.) A. C. H. Gray relinquishes the appt. of Professor at the R.A. Med. Coll.

Lt.-Col. R. R. Lewis retires on retd. pay.

Maj. and Bt. Lt.-Col. (temp. Lt.-Col.) W. C. Smales to be Lt.-Col., vice Lt.-Col. R. R. Lewis.

Maj. T. T. H. Robinson to be temp. Lt.-Col.

Capt. C. V. Macnamara to be Maj. (prov.).

Capt. I. F. MacKenzie relinquishes his temp. commn.

ARMY DENTAL CORPS.

Capts. H. J. Higgins and A. B. H. Cole to be Majs.

TERRITORIAL ARMY.

Lt. W. Niven to be Capt.

J. C. McFarland (late Cadet, Liverpool Univ., Sen. Div., O.T.C.) to be Lt.

ROYAL AIR FORCE.

D. S. Buchanan is granted a commission in the Special Reserve as a Flying Officer.

Flight Lt. G. R. Nodwell is transferred from Class D (ii) to Class D (i).

Flight Lt. W. D. McKeown relinquishes his short service commission on account of ill-health.

INDIAN MEDICAL SERVICE.

Lt.-Col. J. E. Clements retires.

The undermentioned appts. are made: Chuni Lal Ahluwalia, Gopal Singh, Hira Nand Dewan, Kundan Lal Malhoutra, Shiv Parshad Bhatia, and Promode Kumar Sen Gupta to be Lts. (T.C.).

THE NEW SURGICAL WING AT ST. BARTHOLOMEW'S HOSPITAL.

By E. Maxwell Fry, B. Arch., A.R.I.B.A.

The plan of the square of St. Bartholomew's Hospital with its four large eighteenth century buildings shutting it in, is probably familiar to most readers of The Lancet. It will, therefore, indicate the position of the new surgical block which is being opened to-day (Friday) by the Lord Mayor of London, to say that it is entered through the centre doorway of the south block, and that when the scheme of reconstruction of the hospital is completed it will consist of a surgical block, a medical block built over and into the south block itself, and a theatre block midway between. At present every operating case has to be taken across the open quadrangle to the existing theatre in all kinds of weather, so that the provision of the new surgical block removes at one blow one of the patent disabilities of the old unhappy arrangements.

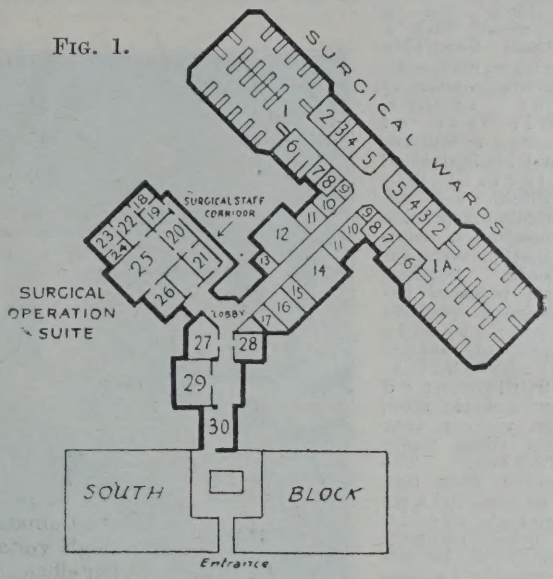
The plan of the new block is governed to a certain extent by the restricted nature of the site, which does not allow of ideal planning. Within these restrictions the architects, Messrs. Lanchester and Lodge, have planned to the utmost limits of enlightened hospital practice, introducing features which even more ideally situated hospitals are without and producing what must be accounted the most scientifically constructed hospital block in the world.

The surgical block is connected on the one side with the nurses' home and on the other with the out-patients and casualty wards, ensuring thereby two essential arterial supplies. With this block running east and west and the south block irremediably fixed in its present position, it will be seen that the theatre block, which should be removed from the wards as an independent unit, is so placed as to lie adjoining the connecting corridor flow, with its large theatre windows facing the steady north light.

Fig. 1 shows the arrangement of one typical floor. There are five of these one above the other, with another floor of laboratories above, and on the roofs a solarium. In the basement will be found the machinery which keeps the services of all kinds in motion, while there is yet another operating theatre for X ray work only.

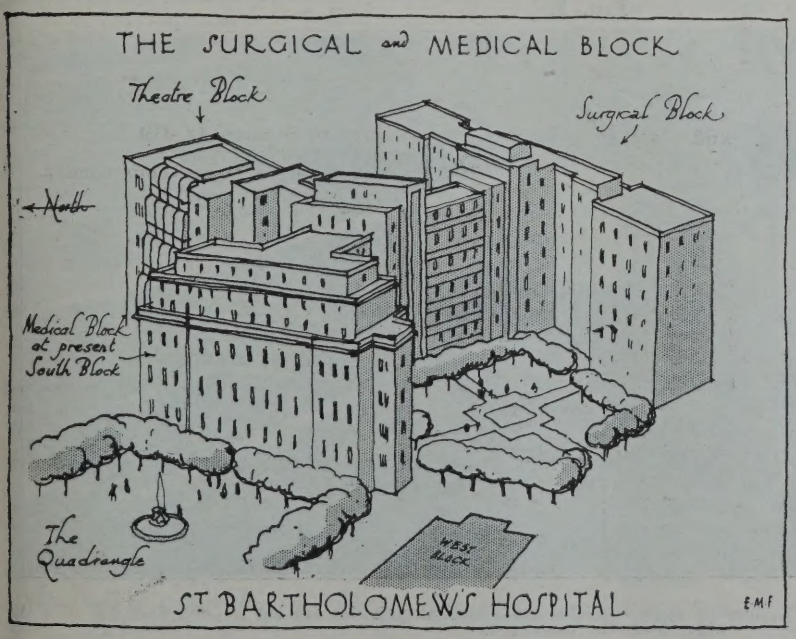
Fig. 2 shows in rough sketch form the appearance of the completed block, and shows why it is necessary to plan a modern hospital not in large single blocks, but in widely deployed wings, cutting in and out as its intention varies, and most important, allowing sun and air to stream uninterruptedly through as many windows as possible. In this connexion it should be remarked that the simple fact of the temperature on one side of a building being slightly lower than on the other is enough to induce cross ventilation without the presence of wind. This natural ventilation is here used to its utmost.

Fig. 1.



(1) Men's ward. (1A) Women's ward. (2) Kitchens. (3) Bath-rooms. (4) One-bed wards. (5) Two-bed wards. (6) Clean "wash-up" rooms. (7) Dirty "wash-up" rooms. (8) Pathological rooms. (9) Patients' clothes rooms. (10) Linen rooms. (11) Sisters' rooms. (12) Special examination and pathological room. (13) Surgeons' laboratory. (14) Bed and main lift. (15) Women's lavatory. (16) Patient's friends waiting room. (17) Men's lavatory. (18) Instrument room. (19) Nurses' dressing room. (20) Surgeons' dressing room. (21) Dressers' and house surgeons' dressing room. (22) Sterilising room. (23) Staircase. (24) Students' observation gallery. (25) Major operation theatre. (26) Anæsthetising room. (27) Visitors' temporary canteen. (28) Temporary dormitory for patients' male friends. (29) Temporary dormitory for patients' female friends. (30) Temporary connecting corridor.

Fig. 2.



The Wards.

The wards, each of 22 beds, supplemented by three beds in two small private wards, are on a sort of dumb-bell plan (Fig. 3) with the service rooms on the connecting corridor duplicated for each ward, male and female. In the wards themselves one is surprised at the absence of the institutional atmosphere. What was chilling in the old hospital plan has been eliminated. The ward is wide instead of long and has a central partition which allows of a regular but not monotonous disposition of beds. Heating is on the panel system and no pipes are visible, but there are two large gas stoves

on the end wall of the wards as a concession to that desire for radiant heat that will keep breaking through our zeal for scientific heating. Open fires might have done even more to promote the feeling of comfort, but they demand extra service.

Each bed is equipped with a care for the physical and mental comfort of the occupant. Wireless, of course, is laid on, and an individual electric light switch, an all-enveloping private curtain, a combination stool for books, brushes, and personal belongings provide sympathetic units of bedside organisation, supplemented by a little stool for visitors that just slides under the bed. The power plug and suction plant point are in another category that will be described later. The glass-faced poison cupboard is the only cupboard in the ward.

FIG. 3.

One of the new wards (the Waring Ward).

THE WARD SERVICES.

The corridor that joins ward to ward carries a complete local service. On one side are, in order, kitchen, bathroom, one-bed and two-bed wards; on the other, clean and dirty "wash-ups," a room for pathological investigations, a patient's clothes room with lockers, and a linen room. The kitchen and clean "wash-up" lead directly from the wards, the remainder opening from the corridor. The small kitchen has an electric refrigerator beside a gas stove of unusual design, including boiling and heating ovens with a little gas stove for cheer. The bath in the bathroom stands free, so that it may be entered from either side. In the dirty "wash-up" are found the controls of the "suction" plant referred to in the description of the ward. This humane and ingenious device replaces the clumsy swabbing and clearing of wounds by a small suction nozzle that does the same work with greater ease and rapidity, carrying the pus and blood away from the bedside at once. The instrument has also other uses for the visiting surgeon.

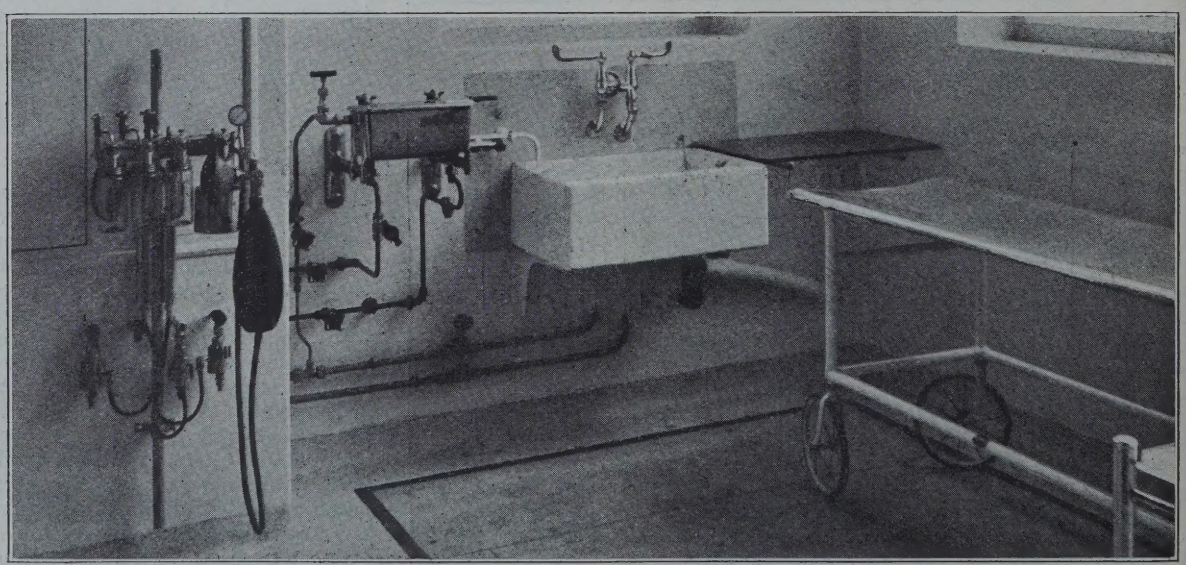
It might be well here to describe the system of one-way lifts that ensure that dirty dressings go down without coming in contact with clean dressings, which come up by another route. In the dirty "wash-ups" bed-pans are stacked on a coil of hot pipes so as to be warmed ready for use if required.

A corridor leading at right angles from the surgical ward block joins the entrance lobby to the theatre block before proceeding to the proposed medical block (as yet unbuilt). On this corridor is found the sisters' room, rather too close to the dirty "wash-up," though this is perhaps unavoidable. On the same side is the main staircase and lift-well, well-equipped rest rooms for visitors waiting to see friends, and lavatories. On the opposite side is the special examination and pathological room, equipped for certain laboratory work and classes.

The Theatre Block.

The design of modern operating-theatre units is a process of exact thinking and stringent elimination of non-essentials. If it achieves beauty it does so because elimination produces simple surfaces, new textures, and abundance of light. In this it moves with the trend of modern design. This theatre block is the most advanced of its kind. The intention

FIG. 5.



A corner of an anæsthetising room, showing apparatus through which anæsthetics are led to each floor by pipes from the basement.

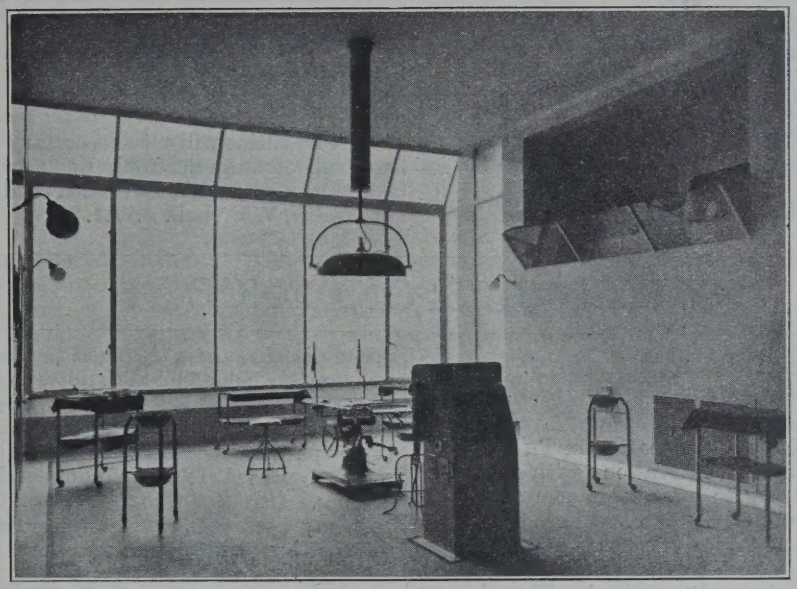
is to bring into the operating theatre only surgeons and nurses who are already washed-up, instruments which are already sterile, and a patient already prepared for operation. Provision is made that incoming and outgoing cases do not meet, and that students may view the operations without setting foot in the theatre.

The whole plan is thus a system of circulation leading to and from the theatre. To achieve this the nearest approach to the theatre is by way of the anæsthetising room (Fig. 5), whence the patient enters. The nurses and surgeons take a longer way round, entering the theatre by a little passage that serves first the dressers and house surgeons' dressing-room, then the surgeons' dressing-room, and finally the nurses' dressing-room, through which is reached the sterilising room. Each party to the operation is thus enabled to change and prepare for the work before reaching the theatre, without loss of time. The circulation is completed by a separate exit for patients.

In one corner is a staircase leading to the spectators' gallery, with a one-way opening door leading from the sterilising room.

The photograph (Fig. 4) of the theatre shows clearly the great north-light window, the operating-table, and anæsthetics column, supplied with a complement of four anæsthetic supplies, beside other equipment. To the right is the gallery for students with glass shield.

FIG. 4.



One of the theatres, showing screened gallery for students, and in foreground, an anæsthetics column which contains also controls and plugs for all electrical apparatus.

FITTINGS, FINISHES, AND MATERIALS.

The washing sinks, constructed with concave walls so as to minimise splashing, with cantilever brackets leaving clear space under them; and "elbow" taps in chromium-plated metal, are models of sane sanitation. A warning light replaces the bell signal here as elsewhere. These signal lights are a feature both of the wards, where they are used to warn particular surgeons of calls in other parts of the building, and of the corridors, where they are fixed over the doors of the small wards to which they are connected. Metal windows are used. The ward windows are large, open at a touch, and open to their full extent. They will also open at the top only for a minimum ventilation.

Hard cements and hard enamels are used in the internal work. In the wards and corridors light entering through the windows is reflected again and again from glossy surfaces until it performs five times its normal function.

The use of materials—not always new, but new in their application—produces a style of architecture where light engenders an atmosphere in which it should be a joy to work, and less of a burden to cure.

Bart.'s is being rebuilt essentially in the atmosphere of our time at one with the architecture of the tubes, of great liners, of aeroplanes, and of all modern works which are stamped with the avid, logical subjugation of matter by reason.

It must have become increasingly evident to the governors that nothing short of a reconstruction of the entire mechanism of the structure would restore the balance of part with part so as to allow the varied work to flow smoothly in and about the whole, and the new surgical block which is but part of a larger block, about which the reconstruction of the hospital is to be grouped. Many of the older blocks are to remain very much as they are; others are to be reorganised internally, while some others again will be demolished and their sites filled with new buildings.

BRITISH POST-GRADUATE HOSPITAL AND MEDICAL SCHOOL.

THE Minister of Health, Mr. Arthur Greenwood, has appointed a Provisional Organisation Committee for the new British Post-graduate Hospital and Medical School.[1] The committee is to report upon (1) the action requisite to lead up to the planning and construction of the medical school, and (2) the form of government appropriate to the hospital and medical school, with special reference to the position of the London County Council as the local authority responsible for the hospital, and to the position of the University of London in relation to the Medical School.

The Chairman is Viscount Chelmsford; the Ministry of Health will be represented by Sir George Newman, Chief Medical Officer, and Mr. Heseltine, as assistant secretary; and the London County Council will be represented by Miss F. Barrie Lambert, M.B., Sir William Ray, Mr. Angus N. Scott, and Mr. L. Silkin.

The representatives of London University will be the Rev. J. Scott Lidgett, the Vice-Chancellor-elect; Mr. S. L. Loney, the Chairman of Convocation and Deputy Chairman of the Court; Mr. H. L. Eason, Superintendent and Senior Ophthalmic Surgeon, Guy's Hospital; and Mr. Edwin Deller, the Principal.

The other members of the Committee are:—

Mr. Donald J. Armour, Senior Surgeon, West London Hospital.

[1] See THE LANCET, 1930, i., 869 and 881.

Lady Barrett, M.S., Dean of the London (Royal Free Hospital) School of Medicine for Women.

Mr. Comyns Berkeley, Surgeon, Middlesex Hospital, and a member of the Radium Commission.

Sir Robert Bolam, Honorary Physician, Royal Victoria Infirmary, Newcastle-on-Tyne, and past Chairman of Council, British Medical Association.

Dr. H. B. Brackenbury, Chairman of Council, British Medical Association.

Mr. H. W. Carson, Senior Surgeon, Prince of Wales's General Hospital, Tottenham.

Dr. H. G. Dain, Chairman of Insurance Acts Committee, British Medical Association.

Lord Dawson, Physician in Ordinary to the King, and Physician, London Hospital.

Prof. H. R. Dean, Professor of Pathology, Cambridge University.

Sir Walter M. Fletcher, F.R.S., Secretary of the Medical Research Council.

Prof. G. E. Gask, Professor of Surgery, London University, and a member of the Radium Commission.

Sir Thomas Horder, Physician in Ordinary to the Prince of Wales, and Physician, St. Bartholomew's Hospital.

Dr. F. N. Kay Menzies, Medical Officer of Health for the County of London.

Lord Moynihan, President of the Royal College of Surgeons; Consulting Surgeon, Leeds General Infirmary, and Emeritus Professor of Surgery, Leeds University.

Mr. H. J. Paterson, Senior Surgeon, London Temperance Hospital, and Honorary Secretary, Fellowship of Medicine and Post-Graduate Association.

Dr. Harold Pritchard, Physician, West London Hospital.

Sir Holburt J. Waring, Surgeon, St. Bartholomew's Hospital.

Mr. Heseltine will act as secretary of the committee, and all communications on the business of the committee should be addressed to him at the Ministry of Health, Whitehall, S.W.1.

CORRESPONDENCE

AVERTIN IN LARYNGOLOGY.

To the Editor of THE LANCET.

SIR,—In the report of the Section of Laryngology, Royal Society of Medicine, appearing in THE LANCET of June 28th, there are observations with regard to avertin on which I beg to offer some comment. It was stated, for example, by one speaker, that "the state of unconsciousness for two hours and sleepiness for three days was, especially in laryngeal conditions, something strenuously to be avoided. The absence of laryngeal reaction in these patients after the use of avertin was very alarming." These remarks were called forth and no doubt justified by the preceding statements of others which unfortunately are not recorded, but I would like to point out that those observations do not apply to the usual effects of avertin when correctly used. When so employed it has never to my knowledge caused sleepiness for three days, and what is more important, the laryngeal reactions return, if they are ever abolished, within a short space of time. This is secured by giving avertin without any preceding opiate or similar drug. I think it would be a pity if the use of avertin, which I have seen to be of enormous benefit to suitable patients undergoing operations on the throat, were to be avoided because of a fear which is really not well founded. I am, Sir, yours faithfully,

London, June 30th, 1930. J. BLOMFIELD.

COLOUR VISION TESTS.

To the Editor of THE LANCET.

SIR,—In an annotation on p. 1360 (June 21st) you dealt with the international standardisation of colour vision tests. The two essentials of a practical test for colour-blindness are that dangerously colour-blind persons only should be rejected by it and that no dangerously colour-blind person should escape detection. The wool test with five test colours allows 50 per cent. of dangerously colour-blind to escape detection and of those rejected by it 50 per cent. are practically normal-sighted. The pseudo-isochromatic tests in common use are those of Stilling, Ishihara, and my card test. In order to ascertain the relative merits of these three tests, 38 consecutive, referred or appeal cases were examined at the Board of Trade with the following results. None of these cases was examined by me alone; at least three persons and often more were present at all the examinations. In every case Capt. Ellery or Capt. Dowdy and the recorder were present. Each candidate was first examined by the pseudo-isochromatic tests and the fact whether he was dangerously colour-blind or not was ascertained subsequently. Ten of the 38 cases were passed and 28 rejected. Of the 28 who were failed 16 failed with all three pseudo-isochromatic tests, but 12 of those rejected passed Ishihara completely and 11 passed Stilling. Of those who were passed 7 showed defects with my card test, and of those who failed all were rejected by my card test, in most cases failing very badly, as for instance not reading card 8, a yellow-green C on an orange ground. The explanation of the difference is that a test for a dichromic will not necessarily detect a trichromic who has three colour sensations red, green, and violet but no yellow sensation, and who is obviously dangerous as shown by the examination with the lantern and spectral tests. In my card test also the pattern is the same on every card, so that the examinee has to judge by colour alone and cannot follow the design of the artist.

An important point to note is that a test which is difficult to the normal-sighted is not necessarily difficult to the colour-blind. This is shown by the number of colour-blind persons who can read Stilling's plates numbered 9 and 10, the reading of which is supposed to indicate very good colour perception. In fact, a test may be constructed which can be read by the colour-blind but not by the normal-sighted. Nagel's anomaloscope is not a satisfactory test as a man may be anomalous without being colour-blind and 90 per cent. of the colour-blind agree with the normal equation.

I am, Sir, yours faithfully,

F. W. EDRIDGE-GREEN.

Board of Trade, S.W., June 28th, 1930.

SUSCEPTIBILITY TO HAY-FEVER.

To the Editor of THE LANCET.

SIR,—There is some evidence that susceptibility to hay-fever is hereditary. It is also a character usually well marked and comparatively easy to trace amongst members of a family. At this time of the year many general practitioners must meet with hay-fever cases whose genetical history could be discovered without much difficulty. Should any of your readers come across such cases and be willing to obtain records of the incidence of hay-fever amongst members of the family over (say) four generations, I should be glad to receive them as I am collecting records of this kind.

I am, Sir, yours faithfully,

H. G. THORNTON.

Bacteriology Department, Rothamsted Experimental Station, Harpenden, June 27th, 1930.

NOISE IN HARLEY STREET.

To the Editor of THE LANCET.

SIR,—As a fellow sufferer I should like to endorse Mr. Ralph Thompson's protest against the persistent din—"noise" is too mild a word—which has afflicted us in this neighbourhood for several weeks past. From the slowness with which the work of building the London Clinic proceeds it is to be feared that we may be subjected to this nuisance for a long time yet. There are noises which are endurable and there are noises which are not. But for this fact I should not write to you, since we cannot expect even a building having so beneficent an intent as a nursing home to be erected like the Jewish temple—noiselessly. The noise that is intolerable is the riveting of the steel girders—sudden, piercing, echoing, and altogether devastating. Friends with knowledge of architecture and building tell me that this exasperating noise could be avoided by the use of special drills, though this would involve an extra expenditure in the cost of the nursing home. May we venture to hope that those concerned will consider it a good investment to incur this additional outlay in exchange for our sympathetic support in the future? I am, Sir, yours faithfully,

Harley-street, W., July 1st, 1930. THOMAS HORDER.

To the Editor of THE LANCET.

SIR,—Could I be allowed to join in with the protest against the hideous noise at the north end of Harley-street? Apart from the almost impossibility of using any sort of instrument or telephone, the constant din is most bewildering and quite inhibits any concentration. I am, Sir, yours faithfully,

Harley-street, June 28th. HORACE HILL, M.R.C.P.

A MANUAL OF FEVERS IN INDIA.

To the Editor of THE LANCET.

SIR,—In your issue of April 26th (p. 939) appeared a letter from Dr. P. T. Patel about the review of his book on infectious diseases (THE LANCET, Jan. 25th, p. 192). Your views, I may say, are shared by most public health authorities out here. Dr. Patel's fear of the introduction of yellow fever is out of date. The old, old bogy about the Panama Canal was drummed into us 20 years ago, and the risk of infection through the Canal Zone is remote in comparison with that of cases imported from Africa to India. Though the risk of yellow fever coming to India along the Imperial Airways route cannot be altogether excluded, Karachi and not Bombay would be the first to get infected.

I am, Sir, yours faithfully,

June 6th, 1930. INDO-MEDICUS.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

COLONIAL HEALTH SERVICES.

ON Thursday, June 26th, the House went into Committee of Supply on the Civil Estimates. Mr. DUNNICO, Deputy Chairman of Committees, was in the chair.

On a vote of £98,306 for the salaries and expenses of the Department of the Secretary of State for the Colonies,

Miss PICTON-TURBERVILL called attention to the question of mui-tsai in the Crown Colony of Hong-Kong, a system under which, she said, little girls from 7 and 8 years of age upwards were deliberately sold for certain sums of money. Such a system, she urged, ought not to exist any longer under the British flag. The hon. Member also drew attention to the practice in the same Colony of selling young girls in connexion with the system of tolerated houses. One way of dealing with this question was to abolish tolerated houses, and she wished to know whether the matter was to be raised at the forthcoming Imperial Conference.

EDUCATION AND MEDICINE.

Mr. HORRABIN raised the question of education in the African Colonies. He said that he wished to emphasise the very strong appeal made recently for the closer relationship between the medical service and the educational machine. It had been remarked that the Board of Education in this country had become more and more a Ministry of Health through the medical examination of children in the schools. That ought to be the case in Africa, where questions of health, hygiene, and sanitation were so much more important. Out of every 1000 babies born in almost every tribe in Kenya, rather more than 400 died every year. He believed that that was a very low estimate.

Miss RATHBONE said that it was hard to see how the requisite changes in administration could be carried out in Africa if the expenditure upon natives was to be bounded and limited by the amount of taxation collected from the natives. Money in matters of social reform was the root of all progress. Indeed, the amount of progress that could be accomplished in health and in education would be the measure of the financial resources available for the purpose. From many workers who had spent years in doing painstaking work for the education and health services of women in Africa she had heard complaints of tiny grants capriciously given, frequently lowered or withdrawn without any particular reason, often in accordance with the demands of economy or because of some anonymous complaint or because money must be made available for some institution in which an administrator was interested. On the health side one heard of great tracts of Africa where hospitals were either non-existent or where they had no female staff, being staffed entirely by men and native boys. This state of things existed although there was an appallingly high infantile and maternal mortality.

Mr. ERNEST WINTERTON said that in 1888 the House of Commons passed a resolution cordially supporting the Imperial and Colonial Governments in their endeavour to suppress the traffic in spirituous liquors in the territories under their influence and control. There had been an increasing sale of spirits in certain parts of the Crown Colonies, which was causing the gravest distress and concern to many people in this country, whether they were associated with the temperance cause or not. They were filled with grave concern at the unsatisfactory nature of the replies so far given, and although they acknowledged that there had been some slight improvement in West Africa and on the Gold Coast during the last two years, there was still much to be done to redeem the established declaration of the House of Commons that the right thing to do was to prohibit the liquor traffic as regarded the native races.

AFRICAN WOMEN.

Dr. DRUMMOND SHIELS (Parliamentary Secretary for the Colonies), replying to the debate, said that the position of women in Africa, maternity and child-welfare, and so on, was the subject of earnest consideration by the Colonial Office, and the existence

of the Colonial Development Fund had given them some encouragement. The terms of reference of the Fund were broadly drawn, and it had been found possible to include in the schemes towards which assistance could be given schemes to develop and assist public health services. A Committee of the Colonial Office had just been sitting to devise the lines along which such assistance should be given, and he was certain that before long they would get very substantial assistance from this Fund for various Colonies which were not very well off. There was no doubt that they had been hampered, especially in certain Colonies, such as Nyassaland, because of the parsimony of the Treasury. But they were now hopeful that in Nyassaland and other parts they might be able with the help of the Colonial Development Fund, not only to assist in public health, but also in the training of subordinate medical personnel, and of midwives, and in other ways to meet the very real need to which hon. Members had called attention. Referring to the question of mui-tsai in Hong-Kong, Dr. Shiels said that last December new regulations were put into force for the registration of employers, and six months were given for the change to be brought about. In July they expected to find out the result of the alteration. It must be remembered that the task of dealing with this question was very difficult. Hong-Kong was a typically Chinese town, in very close association with the mainland, and it was difficult to carry out many of these regulations which were regarded as desirable, but no more mui-tsai were allowed to be brought in, and every effort was being made to carry out the decision which had been made. At the same time there was a difference of opinion, even among British people, as to whether all the results which had been expected from the abolition of mui-tsai would be realised. There was no doubt that there were some disadvantages in the girls being reduced to the status of domestic servants without the protection which they had under the present system. However, it had been agreed that in spite of these disadvantages an effort should be made to get rid of the system. The Chinese authorities had seriously meant to put a stop to the practice of mui-tsai throughout China, but the disturbed state of the country had made those efforts largely ineffective. The policy of the Government was to get rid altogether of the tolerated houses in Hong-Kong.

The debate on the vote was adjourned.

HOUSING AND SLUM CLEARANCE.

ON Monday, June 30th, the House went into Committee of Supply on the Civil Estimates, Mr. R. YOUNG, chairman of committees, in the chair.

On a vote of £12,724,200 for the salaries and expenses of the Ministry of Health,

LACK OF STATE ASSISTANCE

Sir KINGSLEY WOOD moved to reduce the vote by £100. He said that since they had been in office the Labour Government had succeeded in depriving thousands of families in England and Wales of new houses which might have been in existence to-day. There had not been even sufficient State-assisted houses built to meet the ordinary growth of the population and to replace the wastage of old buildings, and if it had not been for private enterprise the housing shortage in the past year would not have been reduced. An army of over 100,000 building operatives walked the streets looking for work in building houses which in many quarters were badly needed, rents had not been reduced, the slums still remained, and the replanning of town and country had made no adequate advance. This was due to the weak, hesitating, and doubtful policy of the Minister of Health.

Mr. E. D. SIMON said that the Ministry of Health was such an overgrown organisation that no Minister could be expected to have very much time to think about these pressing problems. But housing was by far the most important task which the right hon. gentleman had to face, and he believed that it had been very seriously neglected in recent months. He believed that Members in all parts of the House would support the Government in taking some measures to get back from the miserable figure of 50,000 to something approaching the goal they had set before them of 225,000 assisted houses a year.

Miss LEE appealed to the Minister to tackle the problem of rent. She knew that the Government were trying to do it in the Slum Clearance Bill, but there was also the problem of the rents of houses already built. It was no use going on building more houses at rentals which people could not afford to pay.

PROVISION OF THE CHEAP HOUSE.

Sir TUDOR WALTERS said he thought that the real reason why house-building was slackening off was that of the kind of house they had been laying themselves out to build in the last few years—namely, houses of the standard of the Tudor Walters Report, the supply had almost reached the demand. The question of supreme importance now was the provision of the cheap house, the housing of the slum dwellers, the casual workers, and the poorly paid members of the community. But if cheap houses were to be built they must be good houses, and not insanitary huts or hovels, or houses which would degenerate into slums. Such houses must be built on a large scale and they must organise and control the method of building and the supply of materials, and take care that there was no exploitation. They must survey the housing requirements of the whole country and include in their purview slum clearance, the provision of cheap houses to replace slums, and the provision of rural houses at rents which the rural workers could pay. There should be a National Housing Board with four or five men on it who understood the question and would insist upon something being done.

Dr. DAVIES said that of all the failures of the Government the most colossal was their failure in regard to housing. They had expected better results from Mr. Greenwood, who was no novice in this matter, having served as Parliamentary Secretary under the late Mr. Wheatley when he was Minister of Health. But after 12 months of office of the present Government the country was faced with a shocking state of affairs. Why had the Minister of Health not asked Mr. Thomas, when he was Lord Privy Seal, to devote some of the money voted by the House for the relief of unemployment, to assist in the progress of housing? One of the great difficulties which faced local authorities at the present time in regard to housing development was that they were not prepared to take upon themselves fresh financial responsibilities.

MINISTERIAL REPLY.

After further debate,

Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that by every test it was possible to apply it could be proved that this year was much better than last year as far as housing results were concerned. The total number of houses built by local authorities was up, and so was the number built by private enterprise. The total number of houses built between March, 1928, and March, 1929, was 169,532, and no fewer than 201,812 houses had been built this year—i.e., up to March last. As a matter of administration the Government had advised local authorities to hold their hands for slum clearance until the new Housing Bill had passed through the House. They had done so because the authorities under the new procedure would be safer, secondly because the procedure would be quicker, and thirdly because the authorities would be receiving more money. Those were good and sound reasons.

The motion to reduce the vote was negatived by 229 votes to 148.

HOUSE OF COMMONS.

WEDNESDAY, JUNE 25TH.

Fatal Street Accidents in London.

Mr. DAY asked the Minister of Transport whether, in view of the increase in the number of fatal accidents in London during the previous 12 months, what action his department or the London Traffic Advisory Committee were taking to prevent the increase of such accidents in the future; and if he had received any recent reports from the London Traffic Advisory Committee on the subject.—Mr. H. MORRISON replied: My Department, as well as the London Traffic Advisory Committee, are continuously engaged on the consideration of proposals designed to improve the conditions of the streets in London from the point of view of safety, and I am always prepared to consider any such proposals which may be submitted by the local authorities. Two reports of the committee were issued last year on this subject, and were discussed with representatives of all local authorities in the area, and with the associations and societies interested. I hope to be in a position to publish the conclusions reached at the conference at an early date.

Hospital Charges to Air Personnel in Iraq.

Sir GEORGE BOWYER asked the Under Secretary of State for Air whether he was aware that members of the Royal Air Force in Iraq, while in hospital, were deprived of their Colonial allowance, and had to pay 2*s*. 6*d*. a day as a hospital charge, thus undergoing a total loss of 11*s*. 6*d*. a day; and whether he would see that this Colonial allowance was restarted forthwith.—Mr. MONTAGUE replied: My noble friend is aware of the facts stated by the hon. and gallant Member, but he does not see his way to alter the regulations upon this subject. The charge of 2*s*. 6*d*. a day is the normal hospital stoppage for officers, and the issue of Colonial allowance is also properly suspended since it is not an ordinary emolument but an additional allowance granted solely to meet the extra cost of living in a command abroad as compared with the cost at home. When an officer is in hospital and is not subject to the additional expenses which the allowance is intended to cover, its continued issue is clearly not justified.

Sir G. BOWYER: Will the hon. gentleman call for a report on this matter from Iraq, and thus learn of the great difficulties and distress of feeling which there is in that country upon this subject at this time?

Mr. MONTAGUE: I would point out that there is no marriage rate in Iraq at all. The marriage state is not recognised in that respect there.

Cream Regulations in Scotland.

Dr. HUNTER asked the Secretary of State for Scotland if he had made any decision in connexion with the request from a deputation representing the creamery proprietors and wholesale dairymen throughout the country to rescind or amend the Cream Preservative Order.—Mr. JOHNSTON replied: After careful consideration of all the medical and other evidence available and after consultation with my right hon. friend, the Minister of Health, the Secretary of State regrets that he cannot see his way to authorise the withdrawal or amendment of the provisions of the Preservatives Regulations relating to cream.

Mosquitoes and Public Health.

Sir WILLIAM DAVISON asked the Minister of Health whether his attention had been called to the continued increase in the number of mosquitoes in this country; and what action was being taken to combat this menace to the national health.—Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) replied: My right hon. friend is advised that the number of mosquitoes in this country fluctuates from year to year, according to the climatic conditions, but does not show any general increase. In the present year some species (especially the sylvan species) are unusually prevalent. My Department, in collaboration with the British Museum (Natural History), has given attention to this matter for some years past, and a pamphlet on British Mosquitoes and their Control has been published, which contains advice on the best methods of combating mosquito pests. My Department is also prepared on request to advise local authorities on the matter.

THURSDAY, JUNE 26TH.

Medico-Psychological Departmental Hospitals.

Mr. OLIVER BALDWIN asked the Minister of Health if he would consider the setting up of a medico-psychological department to mental asylums, both criminal and non-criminal, in order to attempt the effecting of cures.—Mr. GREENWOOD replied: I cannot undertake to consider this suggestion without a more precise indication of the constitution and functions of the proposed department, and of the necessity for its establishment, having regard to the medical services already available in mental hospitals. I would remind my hon. friend that criminal lunatic asylums are within the jurisdiction of the Home Secretary, and any question in regard to them should be addressed to him.

Smoke Abatement.

Sir NICHOLAS GRATTON-DOYLE asked the Minister of Health what number of local authorities had adopted by-laws on the subject of smoke abatement; what number had no by-laws; and whether it was proposed to take any steps to extend the adoption of such by-laws.—Mr. GREENWOOD replied: 116 local authorities have made by-laws. Although this leaves 1652 without by-laws, the districts without by-laws are largely those where few or no manufacturing processes are found, and many of them are rural. In view of this, and of the powers of proceeding for proved nuisance even without by-laws, I do not think it necessary at present to exercise the power given me by the Act of 1926 of forcing local authorities to make by-laws.

Sir N. GRATTAN-DOYLE: Will the right hon. gentleman bear in mind that this question of smoke abatement is of very vital interest to the public health, and will he not try to ginger up the local authorities so that they will do a little more than they have done?

Mr. GREENWOOD: I am very anxious to encourage local authorities but the process of gingering up is one to which there is a limit.

Midwives Administration.

Capt. EDEN asked the Minister of Health his reasons for refusing to make an order under Section 62 of the Local Government Act, 1929, directing that the borough council of Leamington should become the local supervising authority for the district under the Midwives Acts, 1902 to 1926.—Mr. GREENWOOD replied: I have already informed the borough council that I do not consider it desirable that a separate organisation should be set up for the supervision of midwives in an area in which the number of practising midwives is so small as in this case.

Capt. EDEN: Is the right hon. gentleman aware that this decision is strongly resented by the local authority, and will he indicate the place in the Act where he finds the words on which he has based his decision?

Mr. GREENWOOD: I have not the Act by me, but it was clearly contemplated by the late Government that the powers should only be used in an area where there were a sufficient number of midwives to justify a separate organisation.

Sir KINGSLEY WOOD: I take it that the right hon. gentleman is willing to follow the late Government?

Mr. GREENWOOD: I would not say that, but I must administer the law as it stands.

Capt. EDEN: Does the right hon. gentleman suggest that the local authority is not capable of exercising these powers, and since these words do not occur in the Act, will he reconsider his decision?

Mr. GREENWOOD: As a matter of fact it really is a question of local efficiency, and where the number of midwives in an area is very small, it is clearly advantageous that the administration of the Act should be in the hands of the larger authority.

Defective Children.

Mr. FOOT asked the President of the Board of Education the number of children in England and Wales under the age of 14 for whom, owing to their blindness or other physical disability, no educational provision was at present being made.—Sir C. TREVELYAN replied: The returns furnished by local authorities show that on Dec. 31st, 1929, the number of blind children in England and Wales, under the age of 16, not attending any school or institution was 557; that the corresponding number of deaf children was 305; and of cripples 5461. The returns do not show how many of these children were under the age of 14. It must not be inferred that there is a need for further special school provision to the extent indicated by these figures, as they include some children under the age of compulsory school attendance, and some children prevented by temporary difficulties from attending special schools.

Mr. FOOT: Is the right hon. gentleman satisfied that the number of these children deprived of education is being satisfactorily reduced year by year?

Sir C. TREVELYAN: I am satisfied that the position is getting better, and that there is no special need for increased accommodation.

Private Asylums.

Mr. MACLEAN asked the Minister of Health whether any conditions were imposed upon the licensee of a private asylum as to the conditions under which patients were kept, and the financial charges made while in the keeping of such asylums; and whether he proposed to take power to compel the licensees to submit their accounts to a Government Department for examination.—Mr. GREENWOOD replied: The conditions under which patients are treated in private

institutions are examined by the Visiting Commissioners of the Board of Control who have a duty to inquire among other things as to the fees paid. The Commissioners satisfy themselves that the fees paid are generally reasonable for the accommodation and treatment supplied. The answer to the last part of the question is in the negative.

Bathing Accidents in the Serpentine.

Sir NAIRNE STEWART SANDEMAN asked the First Commissioner of Works whether, in view of the accidents which had occurred recently to bathers in the Serpentine, he would provide a larger measure of supervision than hitherto.

Mr. DAY asked the First Commissioner of Works whether any additional police had been detailed for duty during the mixed bathing sessions on the Serpentine, Hyde Park.—Mr. LANSBURY replied: Police duties in the Park have been rearranged so as to enable two additional male officers to be on duty at the bathing place in the morning, and two in the evening with a policewoman. As to supervision generally, I am satisfied that the present arrangements are quite adequate.

Insanitary Houses in Paddington.

Miss RATHBONE asked the hon. Member representing the Ecclesiastical Commissioners whether his attention had been drawn to the conditions of insanitation and overcrowding, as revealed by the reports of the medical officer of the borough of Paddington, in certain properties in that borough owned by the Ecclesiastical Commissioners; and whether the Commissioners were taking any steps to put their property into the same condition of repair as some other properties under their direct control.—Mr. MIDDLETON replied: The Ecclesiastical Commissioners have not been notified of any report of the medical officer of the borough of Paddington. If they receive notification they will carefully consider what obligations may be imposed upon them by the facts disclosed.

MONDAY, JUNE 30TH.

Lunacy and Divorce.

Mr. HOLFORD KNIGHT asked the Prime Minister whether he had received a memorial, signed by 70 Members of the House of Commons, praying for facilities for the Bill to make certified lunacy of five years and upwards a ground for divorce; whether he was aware that there was a national demand for this reform in the divorce law; and whether he could see his way to grant facilities for the further stages of this one-clause Bill.—Mr. MACDONALD replied: Yes, Sir. As I have already informed my hon. friend by letter, in the present state of Parliamentary business I regret that it is not possible to grant facilities for the Bill referred to.

TUESDAY, JULY 1ST.

Miners and Nystagmus.

Miss LEE asked the Secretary for Mines if he was aware of the inadequate provision made for miners suffering from nystagmus; what steps had been taken since June, 1929, to improve their position; and what measures, if any, were at present under consideration by his department.—Mr. E. SHINWELL replied: Miners suffering from nystagmus are in the same position under the Workmen's Compensation Acts as workmen disabled by accident or other industrial disease. At the same time I am aware of the difficulties to which they are exposed in obtaining re-employment, particularly in the present condition of the industry, and my Department are still considering with the Home Office what steps might be taken to help them in this respect. Clearly the best remedy would be to diminish the incidence of the disease, and investigations with that object are in progress. Whilst medical opinion is by no means unanimous, it is generally agreed that defective light is a contributing factor, and it is satisfactory to note that, with the encouragement of my Department, improved lamps are being introduced at many collieries.

Children and Health Insurance.

Mr. HORE-BELISHA asked the Minister of Health whether his attention had been drawn to a recommendation of the medical officer for Plymouth, in his recent annual report on the health of the city of Plymouth, that children of 15 should immediately become insurable so that their school medical records could be passed to panel doctors and so avoid the present year's gap in health supervision; and whether he proposed to take any steps in the matter.—Mr. HAYES (Vice-Chamberlain of the Household) replied: In the event of provision being made by legislation whereby the minimum age for entry into insurance would coincide with the normal school-leaving age, the question of the transfer of the relevant medical records will receive consideration.

Supply of Quinine in India.

Major GRAHAM POLE asked the Secretary of State for India what progress had been made in the consultations between the Government of India and the Provincial Governments on the question of centralising the whole subject of cinchona cultivation, and the manufacture and distribution of quinine, as suggested by the Royal Commission on Agriculture in India, as a first step towards the reduction of the price of quinine in India to a level at which it would be possible to embark on an extensive anti-malaria campaign.—Mr. WEDGWOOD BENN replied: I have no information later than that given on page 14 of Part I. of the Report on the progress made in giving effect to the Royal Commission's recommendations, a copy of which is in the Library of the House.

The Eight Hours Convention.

Sir KINGSLEY WOOD asked the Minister of Labour whether she could make a statement as to the policy of the Government at the recent conference at Geneva in relation to the suggested revision of the Eight Hours Convention.—Miss BONDFIELD replied: At the meeting of the Governing Body of the International Labour Organisation at which this subject was raised, the representatives of the British Government abstained from voting.

Medical Report on "Red Biddy."

Mr. MCELWEE asked the Secretary of State for Scotland whether the report on "red biddy" was available; and, if not, if he could announce a date when it would be.—Mr. ADAMSON replied: I have received a report from the chief medical officer of the Department of Health for Scotland of which I am sending a copy to the hon. Member.

National Maternity Service.

Mr. FREEMAN asked the Secretary to the Treasury the approximate cost of providing a national maternity service covering the services of a doctor, midwife, and anæsthetic administration.—Mr. GREENWOOD replied: The data required for framing even an approximate estimate of the cost of a service of this kind are not yet available.

REBUILDING OF THE MIDDLESEX HOSPITAL. — The court of governors met on June 24th for the last time in the eighteenth century board room. The old furniture has been stored, and Prince Arthur of Connaught, the chairman, said that the contract for the demolition of the last portion of the old building has been signed, and that of the total sum of £1,100,000 needed for rebuilding only £300,000 remains to be raised.

THE LONDON HOSPITAL.—Lieut.-Colonel W. M. Pryor presided at the annual prize-giving of the London Hospital Medical College and Dental School on June 24th. Prof. William Wright, the Dean, in presenting the annual report, referred to the death of Mr. Thomas Openshaw, consulting surgeon, and Mr. F. A. Hocking, pharmacist, to the hospital. During the past year Dr. Leonard Hill, F.R.S., had received a knighthood, Mr. A. J. Walton had been appointed honorary surgeon to H.M. Household, Mr. A. G. Elliott, the house governor, had been made O.B.E., and Dr. Robert Hutchison had been elected senior censor of the Royal College of Physicians. Mr. Evelyn Sprawson had been awarded the Tomes prize of the Royal College of Surgeons, Dr. F. B. Byrom had been granted a Rockefeller Fellowship, and Mr. A. Birnbaum had scored a notable academic success by winning the Dunn exhibitions in both anatomy and physiology in the March examinations of the University of London. Among contributions made to medicine from the hospital during the past year might be mentioned Prof. William Bulloch's report on the sterilisation of catgut, recent research on the virus of psittacosis, Dr. Dorothy Russell's classification of Bright's disease, and Dr. Donald Hunter's work on calcium metabolism. Dr. Paul Fildes was the general editor of the Medical Research Council's monumental "System of Bacteriology." In presenting the prizes Lord Rayleigh, F.R.S., said that to have a chance of contributing to science "it is far more important to be persevering, and to have a fearless regard for truth, and to keep your eyes open to what is going on about you, than to be very clever or very smart, or very apt in saying things and finding a ready retort to any objection that is made." He warned his audience against vague generalisations and high-sounding phrases, and urged them not to be content with answers until they were definite and satisfying. A great many vague theories were held by doctors and the public, and they needed earnest and conscientious investigation. Lord Knutsford and Dr. Robert Hutchison concluded the proceedings with a vote of thanks.

MEDICAL NEWS

UNIVERSITY OF CAMBRIDGE.—At recent examinations the following candidates were successful:—

M.CHIR.

Alexander Simpson-Smith and C. I. Tuckett.

THIRD EXAMINATION FOR M.B. & B.CHIR.

Part I., Surgery, Midwifery, and Gynæcology.—N. W. Alexander, H. B. Bagshaw, W. I. Bain, C. O. Barnes, J. H. Beilby, A. T. Blair, O. H. Bostock, H. G. H. Butcher, G. F. Carey, H. M. Chappel, W. F. Church, J. H. Conyers, O. J. C. Cotton, R. M. S. Cross, C. A. de Candole, R. M. Dowdeswell, W. S. Dyson, R. H. Fish, E. D. Forster, H. S. H. Gilmer, C. E. D. H. Goodhart, S. E. F. Gooding, A. H. Gurney, G. Hale, J. H. Hall, C. J. K. Hamilton, F. R. T. Hancock, J. O. Harrison, W. Heath, T. C. Jameson Evans, H. D. B. Kelly, R. O. Lee, J. D. McVean, H. Mallinson, F. E. Pilkington, V. H. Riddell, N. H. L. Ridley, H. E. W. Roberton, M. H. Salaman, J. G. Sleigh, E. M. P. Smith, D. J. R. Steen, E. S. Stern, H. C. Stewart, M. Sutcliffe, J. W. P. Thompson, A. W. Vaisey, G. W. Whittall, T. D. G. Wilson, F. G. Wood-Smith, and R. H. Young.

Part II., Physic, Pathology, and Pharmacology.—A. F. Alsop, G. O. Barber, J. H. Bentley, R. M. Bolam, F. G. Booker, W. V. Bowman, W. V. Boyle, O. J. C. Cotton, A. C. Crooke, H. Curtis, C. H. England, J. S. S. Fairley, R. H. Fish, W. R. Forrester-Wood, I. J. Franklen-Evans, G. N. Grose, A. S. Hall, P. E. T. Hancock, H. L. Hoffman, F. W. Holdsworth, L. E. Houghton, E. H. Hudson, M. M. St. G. Johnstone, M. Koettlitz, R. O. Lee, P. G. Levick, A. Lister, D. G. Macdonald, S. McDonald, W. M. Macgregor, F. G. Maitland, R. W. Malim, C. E. P. Markby, H. L. Milles, I. B. Morris, B. C. Nicholson, V. P. Paxon, J. O. Poynton, C. B. Prowse, W. Radcliffe, T. G. Reah, J. Richardson, H. W. Sadlier, J. D. Simpson, G. H. G. Southwell-Sander, R. S. Stacey, E. C. Sugden, C. P. K. Toland, J. C. G. Whitelaw, and F. S. Winton.

UNIVERSITY OF OXFORD.—On June 25th the honorary degree of D.Sc. was conferred on Sir Arthur Keith, F.R.S., and on the following day the degree of B.M. was conferred on G. Campbell.

The Board of Awarders has awarded the Osler Memorial Medal for 1930 to Sir Wilmot Herringham. It is given every fifth year to the Oxford medical graduate who has, in the opinion of the Board of Awarders, made the most valuable contribution to the science, art, or literature of medicine, and who has not previously received the medal.

UNIVERSITY OF MANCHESTER.—Dr. Walter Schlapp has been appointed lecturer in experimental physiology, Dr. J. M. Yoffey assistant lecturer in anatomy, Dr. F. N. Marshall and Dr. Donal Sheehan demonstrators in anatomy, and Dr. I. B. Winter demonstrator in human physiology.

UNIVERSITY OF DURHAM.—On June 26th the honorary degree of D.C.L. was conferred on Lieut.-General H. B. Fawcus, Director-General of the Army Medical Services.

LEAGUE OF NATIONS PUBLICATIONS.—Messrs. George Allen and Unwin, Ltd., have taken over the agency, for Great Britain, Northern Ireland and the Crown Colonies, of League of Nations publications. They will conduct all the League business from 38, Great Ormond-street, W.C. 1 (Museum 1439), and not from their address in Museum-street. The London office of the League for all purposes except the sale of publications, remains at 16, Northumberland-avenue, W.C. 2.

PADDINGTON MEDICAL SOCIETY.—At a meeting of this Society to be held at 9 P.M. on Tuesday, July 8th, at the Great Western Hotel, Dr. G. E. Oates, medical officer of health for Paddington, will give an address on Public Health Topics of General Interest. A resolution for the appointment of a section in connexion with the National Health Insurance Acts will be considered and reports will be received from representatives on other bodies.

RECEPTION TO AMERICAN PUBLIC HEALTH ASSOCIATION.—At the London School of Hygiene and Tropical Medicine on the evening of June 27th Sir Harry Goschen and members of the board of management received members of the Association which is on a visit to Europe to attend international congresses of hygiene in Paris and Dresden, their stay in London being very brief. A number of prominent public health officials were invited to meet them, amongst them officers of the Ministry of Health and of the London County Council, medical officers of health of London boroughs, and representatives of the various central voluntary health associations. During the course of the evening Prof. M. Greenwood gave two ten-minute talks in the statistical laboratory, the first on forecasting the trend of infectious diseases, the second on teaching the elements of statistics to public health students. The other laboratories were open to inspection.

A SURGICAL SCHOLARSHIP.—The Association of Surgeons of Great Britain and Ireland invite applications for a scholarship of £350, to enable the holder to pursue a definite line of research or study at home or abroad. Particulars will be found in our advertisement columns.

HEBREW UNIVERSITY OF JERUSALEM.—The children of Mr. and Mrs. F. Warburg have established a Fellowship in public health in the name of their parents. The fund yields £P.120 a year, and will be awarded annually to a young investigator who is to work in the department of hygiene of the University on a problem of special importance to Palestine. Applications should be made in proper form to the director of the department not later than August 31st.

ENLARGEMENT OF CAERPHILLY HOSPITAL.—Seven years ago Caerphilly District Miners' Hospital was opened with 22 beds. Enlargement speedily became necessary, and a new ward block has now been completed containing 54 beds, together with a new out-patients' department, with consulting-rooms for eye, ear, nose, and throat cases.

COLLEGE OF PESTOLOGY.—The College held a reunion luncheon at the Connaught Rooms on June 25th; the Duke of Sutherland, its new President, occupied the chair, and among the guests were Sir Thomas Horder and Sir Aldo Castellani. Colonel S. P. James, of the Ministry of Health, in proposing the health of the College, said that the Ministry sympathised with its aims and recognised their importance to the national health, but that the help of the public, financial and practical, was more valuable than official sympathy. The President appealed for funds to carry on the work of investigation and enlightenment.

ORDER OF THE HOSPITAL OF ST. JOHN OF JERUSALEM.—The King has sanctioned the following promotions in and appointments to the Venerable Order of the Hospital of St. John of Jerusalem:—As Knight of Grace: Dr. W. E. Audland. As Commanders: Dr. L. F. R. Knuthsen, Dr. Ll. A. Morgan, Dr. A. Ellison, Dr. J. F. Arlidge, Dr. J. E. Nevins, Dr. W. M. Cairns, Dr. K. H. Beverley, Lt.-Col. S. M. W. Meadows, R.A.M.C., and Dr. J. H. Chambers. As Officers: Sir John W. Thomson-Walker, Dr. F. Romer, Dr. E. S. Jackson, Dr. Tom Sanderson, Dr. A. J. Young, Dr. H. J. Clutterbuck, Dr. G. S. Phillips, and Dr. J. M. Wilson. As Serving Brothers: Dr. H. C. Darby, Dr. T. Bell, Dr. F. B. G. Holmes, Dr. H. G. Ramsbottom, Dr. N. J. L. Rollason, Dr. E. J. Deck, Dr. Charles Edgar Whitcher, and Dr. E. E. Dufty. As Serving Sister: Dr. Catherine M. Edgerley.

THE CHILDREN'S CLINIC.—A meeting was held in the Women's Service Hall on June 25th in support of the clinic established at 85, Clarendon-road, London, W., for the observation and treatment of nervous and delicate children. Prof. Winifred Cullis, who presided, said that in this country new advances in medicine tended to grow out of the hospital system, first as voluntary enterprise, and then as a link in some way or another with organised medicine. She believed this clinic was the beginning of a movement which had come to stay. Miss Coster, Principal of Wychwood School, Oxford, spoke of the need of emotional training rather than indiscriminate outlet, and pointed out how psychological maladjustment arose from emotional stresses to meet which the child had not been properly prepared. Dr. Margaret Lowenfeld, the honorary medical director of the clinic, set out the relationship of the work of the clinic to national and economic problems, pointing out that £300,000 was spent last year on the maintenance of boys and girls between the ages of 16 and 21 in prison, while in her view it would cost only £30,000 a year to keep them out. Moreover, that £300,000 spent on prisons produced no improvement, and in many cases even produced deterioration. She said that the child world was dream world made out of phantasy, and had little contact with actual life; a child built all his life out of pictures which were the fulfilment of his wishes. In the clinic the child was set to play; his make-believe world came to light, and his desires were understood and adjusted to socially useful ends. Maladjustment and delinquency in children arose from physical and emotional causes. The clinic was staffed by a team of workers who attacked the problem from all sides: social, constitutional, psychological, and biochemical. It had been constructed on lines which allowed of the use of records of every case as permanent material for study. The band of people representing the clinic had used every effort to bring the clinic to its present stage, and now appealed to the public to enable it to be developed.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

SATURDAY, July 12th.—3 P.M. (at the East Suffolk and Ipswich Hospital, Ipswich) Annual General Meeting. Mr. F. F. Ward: The History of the Development of a Venereal Disease Clinic. (Meeting preceded by luncheon for members and their friends at the White Horse Hotel.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

WEDNESDAY, July 9th.—5 P.M., Dr. Harvey Cushing: Neurohypophysial Mechanisms from a Clinical Point of View. (Lister Lecture.)

THURSDAY.—2.45 P.M., Prof. H. R. Dew: Hydatid Disease: Some Interesting Complications. (Hunterian Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, July 7th, to SATURDAY, July 12th.—VICTORIA PARK HOSPITAL, Cambridge Heath, E.. Tues., 2 P.M., Demonstration on Heart Cases by Dr. Shirley Smith. No fee.—SOUTH LONDON HOSPITAL FOR WOMEN, 88, Newington-causeway, S.E. Wed., 2 P.M., Demonstration of Cases by Miss Margaret Basden. Open to women graduates only. No fee.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, July 7th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations

FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M., Medical, Surgical, and Children's Diseases Clinics. Operations.

Appointments

BRAIN, W. RUSSELL, D.M., M.R.C.P., has been appointed Assistant Physician to the Royal London Ophthalmic Hospital.

Certifying Surgeons under the Factory and Workshop Acts: BEWES, A. G., L.R.C.P. Lond., M.R.C.S. (Southend); and ROUTH, J. L., L.R.C.P. Lond., M.R.C.S. (Okehampton).

City of London Maternity Hospital: MARSHALL, C. M., M.B., Ch.B. N.Z., F.R.C.S. Eng., Resident Medical Officer; ALLINSON, F. W., M.B., B.S. Lond., Assistant Resident Medical Officer.

Vacancies

For further information refer to the advertisement columns.

Aberdeen Royal Hospital for Sick Children.—Res. H.P. Two Res. H.S's. Also Hon. Asst. S. to Ear, Nose and Throat Dept.

Aberystwyth Infirmary and Cardiganshire General Hospital.—H.S. £200.

All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley-road, N.W.—Hon. Surgical Registrar.

Association of Surgeons of Great Britain and Ireland.—Surgical Scholarship. £350.

Barnsley, Beckett Hospital and Dispensary.—H.P. £200.

Bath, Royal United Hospital.—H.P. £120.

Birmingham, Highbury Hospital, Moseley.—Res. Asst. M.O. £300.

Birmingham, Selly Oak Hospital.—Surgeon. £700.

Blackburn Royal Infirmary.—Res. H.P. £175.

Bolingbroke Hospital, Wandsworth-common, S.W.—Res. M.O. Chiefly surgical. £200. Also H.P. At rate of £120.

Bolton County Borough.—Asst. M.O.H. and Asst. School M.O. £500.

Bournemouth County Borough, Malvern and Winton Infant Welfare Centres.—Medical Attendant. 1½ guineas per session.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

British Red Cross Society, Clinic for Rheumatism, Peto-place, Marylebone-road, N.W.—Hon Consulting Surgeons, &c.

Central London Ophthalmic Hospital, Judd-street, St. Pancras, W.C.—Sen. and Jun. H.S.'s. At rate of £120 and £100 respectively.

Charing Cross Hospital, W.C.—Res. Anæsthetist. At rate of £100.

Colchester, Royal Eastern Counties' Institution for Mentally Defective.—Clin. Research Worker. £600.

Croydon General Hospital.—Hon. Anæsthetist.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £150.

Doncaster Royal Infirmary.—Three H.S.'s, and One H.P. All at rate of £150.

Dudley, Guest Hospital and Eye Infirmary.—Asst. H.S. £150.

Egyptian University Faculty of Medicine.—Prof. of Hygiene. £E.1500.

Essex, Administrative County of.—Asst. M.O.H. £500.

Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £120.

Gloucester, Gloucestershire Royal Infirmary, &c.—H.P. and 2nd H.S. At rate of £135 and £100 respectively.

Halifax Royal Infirmary.—3rd H.S. At rate of £125.

Hertford County Hospital.—H.P. At rate of £150.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. At rate of £50.

Hospital for Sick Children, Great Ormond-street, W.C.—Med. Reg. and Pathologist. £300.

Ilford, King George Hospital.—Hon. Neurologist.

Indian Medical Service Commissions.

Inverness Royal Burgh, P.H. Dept.—Asst. M.O.H.

Ipswich Borough Mental Hospital.—Med. Supt. £700.

Kensington, Fulham and Chelsea General Hospital.—Res. Cas. M.O. At rate of £100.

Lancaster County Mental Hospital.—Temp. Asst. M.O. Seven guineas weekly.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool, David Lewis Northern Hospital.—Medical Tutors and Registrars. Each £175. Also Four H.S.'s, and Two H.P.'s. Each £100.

Manchester, City of, Education Committee.—Asst. School M.O. £600.

Manchester Northern Hospital, Park-place, Cheetham Hill-road.—Sen. H.S., and Jun. H.S. £130 and £100 respectively.

Manchester Royal Eye Hospital.—Jun. H.S. £120.

Manchester Royal Infirmary, Central Branch, Roby-street.—Jun. H.S. and Cas. O. At rate of £100.

Manchester, St. Mary's Hospitals.—Four H.S.'s. At rate of £50.

Manitoba University.—Asst. Professor of Anatomy. 3500 dollars.

Middlesbrough, North Ormesby Hospital.—H.P. £120.

Middlese County Council.—Asst. M.O. £600.

Mile End Hospital, Bancroft-road, E.—Deputy Med. Supt. £600.

Miller General Hospital, Greenwich-road S.E.—Cas. O. £150.

Ministry of Health, Government Lymph Establishment. Hendon.—Bacteriologist. £700 and bonus.

National Hospital, Queen-square, W.C.—H.P. £150.

Newark General Hospital.—Res. H.S. At rate of £150.

Newcastle-upon-Tyne, City Hospital for Infectious Diseases.—Res. Med. Asst. £350.

Newport, Mon., Royal Gwent Hospital.—Hon. Radiologist.

Northampton General Hospital.—Asst. H.S. At rate of £150.

Norwich, Norfolk and Norwich Hospital.—H.S. £120.

Northwood, Mount Vernon Hospital.—Gynæcologist.

Nottingham General Hospital.—H.S. At rate of £150.

Oldham County Borough Education Committee.—Asst. Sch. M.O. £500.

Plymouth City Hospital.—Med. Supt. £1000.

Plymouth, South Devon and East Cornwall Hospital.—H.S. At rate of £100.

Poplar Hospital for Accidents, East India Dock-road, Poplar, E.—Second Res. O. At rate of £175.

Portsmouth Royal Hospital.—Cas. O. At rate of £100.

Preston and County of Lancaster Royal Infirmary.—H.S. £150.

Preston, Biddulph Grange Orthopædic Hospital.—Radiographer. £200. Also Jun. H.S. At rate of £150.

Prison Medical Service.—Medical Officer, Class II. £350 and bonus.

Queen's Hospital for Children, Hackney-road, E.—Clin. Asst. for Orthopædic Dept. 5s. each attendance.

Reading, Royal Berkshire Hospital.—Cas. O. and Res. Anæsthetist. Each at rate of £150.

Reading University.—Independent Lecturer in Agricultural Bacteriology. £400–£500.

Rhondda U.D.C.—Asst. M.O.H. and Asst. School M.O. £500.

Royal College of Surgeons of England.—Examiner in Dental Surgery.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. for Out-patient Department. £150.

Salford Royal Hospital.—H.P. and Cas. H.S. Each at rate of £125.

Sheffield Royal Hospital.—H.S. to Ear, Nose and Throat Dept. Also Res. Anæsthetist. Each at rate of £80.

Sheffield Royal Infirmary.—Two H.S.'s. Also Ophth. H.S. Each at rate of £80.

Sheffield, Jessop Hospital for Women.—Registrar and Obstetrical Tutor. £500.

Shrewsbury, Royal Salop Infirmary.—Res. Surg. O. £200.

St. John's Hospital Lewisham, S.E.—Hon. Surgeon, also Res. M.O. £250.

St. Thomas's Hospital.—Jun. Asst. to Venereal Dept. £250.

Swindon and North Wilts Victoria Hospital.—Res. M.O. At rate of £125.

Taunton and Somerset Hospital.—Jun. H.S. At rate of £100.

Truro, Royal Cornwall Infirmary.—H.S. £170.

Walsall General Hospital.—Cas. H.S. At rate of £120.

Warwickshire C.C.—Asst. County M.O.H. £500.

Weir Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £150.

West African Medical Staff.—M.O.'s. Each £600.

West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Jun. H.P. At rate of £100.

West London Hospital, Hammersmith-road, W.—Res. Asst. Phys. £300.

Winchester, Royal Hampshire County Hospital.—H.P. £150.

Wolverhampton Royal Hospital.—Cas. O. and H.S. to Ear, Nose and Throat Dept. At rate of £125.

Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Newburn (Northumberland).

NOTES, COMMENTS, AND ABSTRACTS

MENSTRUATION IN SCHOOLGIRLS.*

A SURVEY BASED ON REPLIES TO A QUESTIONAIRE.

THE subject of menstruation is of importance to all persons responsible for the health of women or girls, and the present inquiry was undertaken to fill some obvious gaps in current knowledge. In the year 1925 the London Association of the Medical Women's Federation were approached by a medical officer of health with a request for information about the effect of school games on menstruation, and what rules concerning playing at these periods were usually prescribed to pupils. The Association found that although their members could contribute a great mass of clinical experience on this subject, there was a surprising lack of exact data on this as, indeed, on most other points dealing with menstruation in the normal girl. The difficulty had always been that of finding suitable avenues of approach to a sufficiently large sample group of healthy girls, and of overcoming the obvious objections to questioning adolescents on such an intimate matter.

The Association were fortunate in learning that the Ling Association of trained gymnastic instructresses was about to initiate an inquiry on the same subject. They agreed to join forces and later the generous coöperation of the Headmistresses Association was secured. A questionaire, approved by representatives of the three societies, was drawn up and circulated by the headmistresses to several hundred schools. As it was all important that the questionaire should prove acceptable to mistresses and parents, some of the original points on which the medical women had desired information had to be omitted or greatly modified. The questionaire sent was as follows:—

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

Inquiry dealing with Menstruation in School-children.

(To be filled up in respect of girls who have attained their 14th birthday, and who have menstruated.)

1. Name or Number.....
2. Age.....
3. Previous history:
   - (A) Illnesses (cross out any of the following illnesses the child has not had)—
     (*a*) Rheumatic fever. (*b*) St. Vitus' dance. (*c*) Heart disease.
   - (B) Has the girl had any other illnesses, infectious or otherwise, which kept her away from school? If so, what were they? Give date and duration if possible.
   - (C) Has she had any operation? If so, what was it for? Give date.
4. Age at which monthly periods began.
5. Are they regular? If so, how many days elapse between the first day of the one period and the first day of the next? If not regular, state as precisely as possible how often they occur.
6. Is a record kept of the occurrence of the period?
7. How many days does the period last?
8. Does the girl have any pain? If so, does it come on (*a*) before the period? (*b*) During the period? (*c*) After the period?
9. Does the girl do exercises or play games during the period?
10. Does she wish to? If not, what reason is given?
11. Is she definitely known to have headache at this time?
12. Is she constipated at this time?
13. Do her general health and happiness appear to be as good as usual during the period?
14. Has she ever had to stay away from school owing to periods?

Remarks.—Date. School which the child attends. Signature of parent or school doctor, or gymnastic mistress, or headmistress. N.B.—If preferred, initials may be given instead of the full signature.

The response was unexpectedly large, and the committee cannot express too strongly their thanks to the large number of those who so materially assisted in filling in the forms. Over six thousand questionaires were returned completed, filled in by headmistresses themselves or by assistants on their staff, gymnastic mistresses, the school doctor, parents or in some instances by the children. Such a mass of material has been no easy matter to handle, and the committee were fortunate in securing Prof. M. Lucas Keene and Miss Ethel Hewer, D.Sc., to undertake the scientific review and to direct the course of the analysis.

Satisfactory results could, however, only be obtained under the guidance of an expert statistician, and Prof. Major Greenwood kindly allowed a member of his staff, Miss E. Newbolt, to make a preliminary analysis. She was unfortunately unable to continue the investigation, and Dr. Doris Baker was asked to bring the work to completion. This she has done under the kind direction of Dr. Peter McKinlay, to whom, with Prof. Major Greenwood, the committee is greatly indebted. The tables recording the detailed figures are available for inspection; for reasons of space a few only are here included.

The schools from which replies were received were grouped as follows:—

	Number of schools.	Number of returns.
(*a*) Day schools—		
1. High schools	23	1495
2. Secondary schools	54	3209
(*b*) Boarding schools—		
1. Private	25	1220
2. Charitable institutions	10	175
	112	6099

Statistical Analysis of Results.

The main points which the committee desired to investigate were:—

1. Characteristics of the menstrual period: (*a*) regularity; (*b*) duration.
2. Extent of disability from menstruation during adolescence as indicated by: (*a*) incidence of pain; (*b*) effect on general health and happiness; (*c*) absence from school; (*d*) relation to physical exercise.
3. Relation of length of menstrual history to the above.

Characteristics of Period.

REGULARITY OF PERIOD AND LENGTH OF INTERVAL.

The frequency distribution of the intervals between the periods (reckoning from one onset to another) shows a definite peculiarity—i.e., the lack of any general tendency to fill smoothly on both sides of a maximum value. (For actual numbers see Table I.) Several peaks are apparent, indicating that a heaping up of cases occurs at weekly intervals, three, four, five weeks, with the greatest frequency at 28 days. Similar predilections for round numbers are found in the records of age-distribution at census enumerations, and these should make one hesitate to believe that the detailed distributions of interval given here represents the *true* frequency at each of these days. The results may be divided into three groups:—

(1) Above 28 days and varying	36·3
(2) 28 days or varying above and below	41·7
(3) Below 28 days and varying below	21·9

The percentage recorded as 28 days exactly was 39·2. It was found that the figures given by girls whose actual records were kept, when extracted separately, do not vary significantly from the figures of *all* samples.

Regularity and pain.†—The incidence of regular

* Being a report on an inquiry into menstruation in schoolgirls based on over 6000 replies to a questionaire by a committee of the London Association of the Medical Women's Federation.

† "Pain" includes all degrees, however slight and transient.

periods is definitely slight, though greater among those girls not suffering from pain. The percentage of "regulars" among the "no pain" group was 79·6, compared with 73·4 among the remainder.

Classified in relation to the separate type of pain groups the incidence of regularity is as follows:—

No pain	79·6	
Pain before period	74·4	76·8
„ „ „ (slight)	82·3	
Pain during period	75·0	75·8
„ „ „ (slight)	77·4	
Pain after period	66·7	62·5
„ „ „ (slight)	60·0	
Pain before and during	59·3	59·6
Pain before, during, and after	69·2	

Length of interval and pain.—For the purposes of correlation the distribution of pain has been classified according to its presence or total absence. The interval has been treated in three broad categories:—

(1) Above 28 and varying above.
(2) 28 exactly.
(3) Below 28 and varying below.

The figures, however, do not show results of any positive importance, and the whole series taken together suggests an absence of definite relationship between the two factors. The general conclusion would appear to be that the presence or absence of pain is not dependent on the length of the interval.

(*b*) DURATION OF PERIOD.

The average duration of the periods in all girls in the three groups of schools is as follows:—

High schools	5·14 days.
Secondary schools	4·92 „
Boarding schools	4·76 „
Residential institutions	4·47 „

The returns for individuals were, of course, stated in days and not in fractions of days. The limits of variation were 2 to 14 days, the mean being four or five days. It was noted, however, that some of the girls whose period lasted 14 days played games throughout and made no complaint of pain or ill-health.

As regards the effects of *exercise*, the average duration in the two groups (1) taking full exercise throughout the period, (2) limiting their exercise, shows a difference which is certainly statistically significant. (For actual figures see Table II.)

Girls taking full exercise	5·20 days.
Girls limiting exercise	5·33 „
Difference	0·1382 „

TABLE II.—*Duration and Exercise.*

Days.	Exercise—		Days.	Exercise—	
	Full.	Limited.		Full.	Limited.
1	—	1	7	342	253
2	4	3	8	17	27
3	130	64	8+	11	9
4	637	280			
5	1287	748	Total..	3204	1792
6	776	407			

There is, therefore, a shorter average duration in girls taking exercise throughout the period, but it is impossible to say whether exercise shortens the period or whether the girls with shorter periods tend to take exercise throughout.

There is also a slight but definitely significant relation between *pain* and the duration of the periods. If we consider first of all the two broad groups, those with pain and those without, we find the average duration as follows:—

Girls with no pain	4·81 days.
Girls with pain	5·10 „

The greatest difference is in those suffering both *before* and *during* the period (5·28 days), and is least in those suffering pain only *before*.

No pain	4·81
Pain before	4·88
Pain during	5·12
Pain during and before	5·28

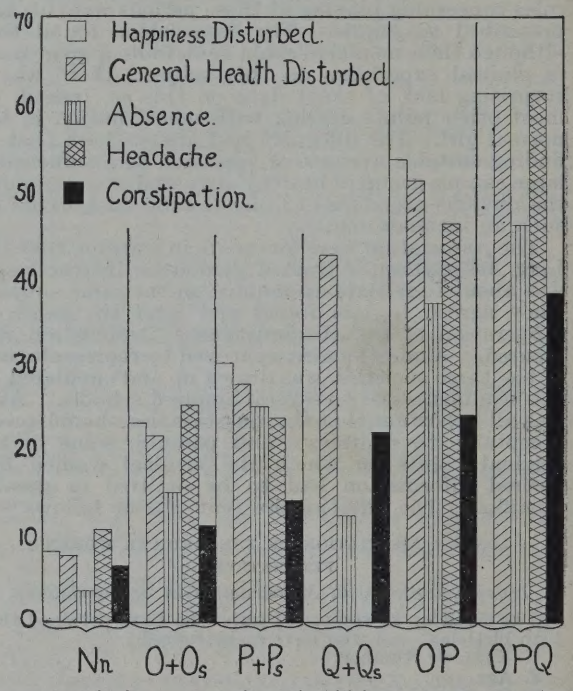
Correlation ratio 0·246 is definitely significant.

Extent of Disability from Menstruation in Adolescence.

INCIDENCE OF PAIN.

The records for three of the groups of schools—the high schools, the secondary schools, and the boarding schools—give results showing a fairly close resemblance one to another. (See Fig. 1.) Something

FIG. 1.



Percentage incidence of various disabilities during the menstrual period. Nn = No pain. O = Pain before period. Os = Pain before period sometimes. P = Pain during. Ps = Pain during sometimes. Q = Pain after. Qs = Pain after sometimes. O.P = Pain before and during. O.P.Q. = Pain before, during, and after.

more than half the total in each group—i.e., 52·4, 55·4, and 59·9 per cent.—are recorded as not suffering from pain, however slight or transient, at any time during the menstrual period. The remaining group (the charitable institutions) show a considerably higher proportion of "no pain" than this—i.e., 71·7 per cent. of the total.

The wide discrepancy between this and the other three groups suggests the influence of some special factor at work here, possibly a difference in the methods of recording the data. As the numbers in this group were very small, they are omitted in any combined work. Considering then only the first three groups, the records show that among those suffering some pain, the majority, slightly more than half (25·9 per cent.) falls in the group *during the period* whereas a negligible proportion only suffer *after* the period (1·6). Only 10·4 claim to suffer *before* the onset, and about the same number (6·8) *before and during* the period. Sufferers over the long stretch, before, during, and after the period, are an insignificant fraction of the whole. (For distribution of pain, see Table III., A, B, C, and D.)

In the three groups of schools the variations in frequency of pain are not very large. The chief differences are in (1) the main group of "no pain," where the high schools show a smaller proportion than the boarding schools; and in (2) the group showing pain *during* the period, in which the pro-

A.C. = High schools. A.D. = Secondary schools. B.F. = Boarding schools. B.E. = Residential institutions. Nn. = No pain.
O. = Pain before period. Os. = Pain before, sometimes. P. = Pain during. Ps. = Pain during sometimes. Q. = Pain after.
Qs. = Pain after sometimes. O.P. = Pain before and during. O.P.Q. = Pain before, during, and after. N.R. = Not recorded.

portion is greatest in the high schools and least in the boarding schools.

The figures for incidence of pain have been taken out separately for those with a menstrual history of one year or less. Comparison of these with the total series shows that the exclusion of those with short history reduces the proportion with no pain. The increased frequency of pain with longer experience chiefly falls in the group "pain *during* the period." The suggestion conveyed by the figures is that at the *onset* of menstruation fewer suffer pain than later in life, the chief increase being among girls suffering pain *during* the period.

The degree of pain was not specifically asked for in the questionaire, but 700 returns stated that pain was "slight." Only 61 out of 6099 complained that the pain was "bad" or "much" or "severe."

Schools—	Slight.	Severe.	Total returns.
High	218	13	1495
Secondary	366	43	3209
Boarding	116	5	1220

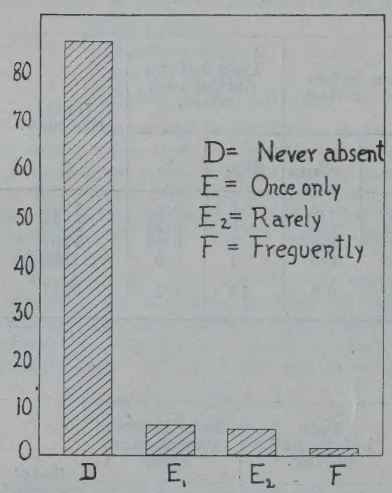
EFFECT ON HEALTH AND HAPPINESS.

The total number of those recording an adverse effect on health and happiness was as follows:—

Schools—	Happiness disturbed.	General health disturbed.	Headache.	Constipation.
High ..	25·43	23·44	19·49	12·78
Secondary ..	17·86	16·50	19·06	9·89
Boarding ..	14·51	15·28	16·29	8·64

Thus headache, disturbed happiness, and interference with general health are in that order the most frequent concomitant effects of menstruation recorded. The association with pain is marked. The disturbance of health and happiness are nearly four times (3·7) as heavy an incidence in the girls complaining of pain as in the "no pain" group. Headache and constipation are only two to three times as frequent in the "pain" group.

FIG. 2.



Percentage of absences during menstrual period.

Inspection of the results for the individual pain groups shows a fairly definite order. The incidence of all these concomitant factors is lowest *before*, increases *during*, and still further *after*, and reaches the highest value in those with the long stretches of pain *before, during and after* the period.

ABSENCE FROM SCHOOL.

The total number of girls recording absence from school is as follows. (See Fig. 2.)

Schools—	Rare.	Frequent.
High	13·85	1·95
Secondary	12·6	1·07
Boarding	7·65	0·84

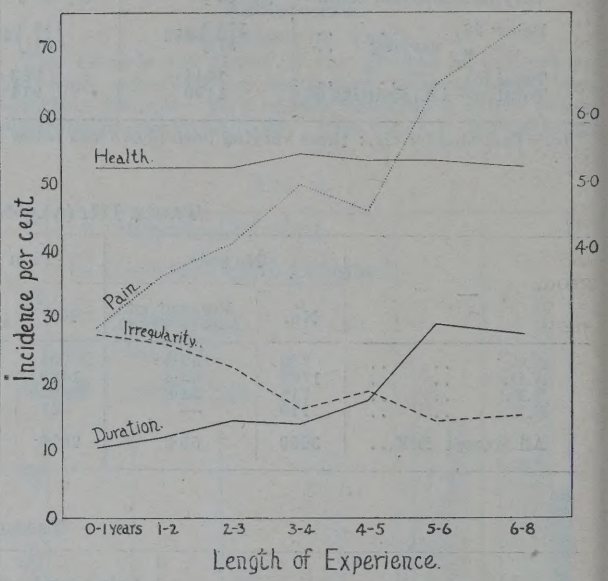
The figures for the three groups of schools have been classified as (1) no absences, (2) absent once only, (3) absent occasionally, (4) repeated absences.

	Schools.		
Absent—	High. Per cent.	Secondary. Per cent.	Boarding. Per cent.
Never	83·3	86·5	91·9
Once	8·6	6·6	3·3
Rarely	6·1	5·8	3·8
Repeatedly	2·0	1·1	0·9

The average of those who are never absent is, therefore, high, while serious absences are a negligible proportion—under 2 per cent.

Absence from school may, therefore, be considered an infrequent event. It is six times more common among those who record pain, and habitual absence is ten times more frequent in this group.

FIG. 3



Relation of health, pain, irregularity, and duration to length of menstrual history.

EXERCISE.

The practice of the three groups of schools in regard to exercise‡ during the period show quite an appreciable difference.

Schools—	Per cent.	
High	57·8	exercise during the entire period.
Secondary	69·8	
Boarding	40·9	

The difference is due to the greater restrictions on exercises (either throughout the period or for the first two or three days) in the boarding schools than in day schools.

Pain and exercise.—The returns have been classified into: 1. (*a*) Groups with pain, and (*b*) No pain. 2. (*a*) Full exercise throughout the period, and (*b*) Exercise limited.

	GROUPS WITH PAIN. Exercise—		NO PAIN. Exercise—	
	All the time.	Limited.	All the time.	Limited.
High ..	49·3	50·7	72·7	27·3
Schools—				
Secondary ..	66·7	33·3	83·3	16·7
Boarding ..	31·5	68·5	50·8	49·2

The results show association of quite a definite kind between the two factors of pain and exercise, the proportion of those taking exercise all the time who experience no pain being substantially greater than the proportion among those who do *not* have exercise all the time. The correlation could, of course, be interpreted the opposite way by saying that a greater proportion of girls who have no pain take exercise throughout the period than of those who *do* have pain. The figures only show that the two factors, absence of pain and exercise, are significantly associated; they cannot show which is cause and which is result. Whether, in fact, it is the taking of exercise which tends to reduce the frequency of pain, or whether it is the absence of pain which permits the indulgence in exercise the figures do not show.

‡ "Exercise" here only refers to formal exercises and organised games and *not* to out-of-school activities.

Relation of Length of Menstrual History to Above.

The length of menstrual history is found to range from under one year to eight years, and has been worked out for tabular presentation at yearly intervals. (See Fig. 3.) The incidence of *disturbance of general health, pain, and absence from school* is found to increase steadily and gradually throughout the whole range of the menstrual histories here recorded. (The groups 6 to 7 years and 7 to 8 years have been combined owing to the smallness of the numbers available.) Next in order comes *disturbance of health*, where the rate increases nearly threefold from the beginning of menstrual history till the end of the eighth year. *Pain* (all degrees) increases from 28 per cent. to 73 per cent. within this period. On the other hand, there is a definite reverse movement in the case of *irregularity*. Here there is a substantial decrease in incidence with increasing length of history, the rate falling from 27 per cent. in the first year to 15 per cent. in those of 6 to 8 years' experience. The average *duration* of the period has been calculated for each group, and there is obviously no evidence of association —the duration of menstruation does not change significantly with increased length of menstrual history.

Summary.

1. The distribution of the interval between the periods is peculiar and suggests a predilection for whole weeks—i.e., the frequencies recorded at 21, 28, and 35 days seem exceptionally high. The most frequently occurring interval is centred on 28 days.

2. The presence or absence of pain does not seem to be sensibly correlated with length of interval.

3. The regularity of the period is significantly but slightly related to pain, the proportion recorded as regular being more in the "no pain" group than in all others.

4. The average duration of the period is definitely but very slightly lower among girls taking full exercise throughout the period.

5. The duration is longer (about one-third of a day) in those who suffer pain than in those who do not.

6. Slightly more than half of the girls studied do not suffer pain or discomfort, however slight, at any time during the menstrual period.

7. Of those recorded as suffering pain, the majority suffer *during* the period only.

8. The difference in the incidence of pain in the three groups of schools (high, secondary, and boarding schools) when analysed separately are not very large.

9. The distribution of the number of girls taking full exercise throughout the period in the three groups of schools shows appreciable differences, and contrasts with the much smaller differences between the groups of schools in respect of incidence of pain.

10. Pain and exercise seem to be definitely related one to another, but from these data it is impossible to suggest which is cause and which is effect.

11. The incidence of disturbed happiness or general health, headache, and constipation is definitely related to the presence of pain, the influence being most apparent in the case of disturbed health and happiness and least in headache and constipation.

12. Absence from school is definitely related to the occurrence of pain, but regular or frequent absence is very rare at any time during adolescence.

13. The time in the menstrual cycle at which the pain occurs is related to all the above factors. The incidence of all of them increases steadily and gradually in the following order: With no pain; pain before the period; during the period; after; and before, during, and after the period.

14. Comparison of the whole series and that obtained by excluding girls with a history of one year or less suggests that at the early period of menstruation a smaller proportion of girls suffer pain than later, during the age-period studied (onset to 18).

15. Analysis of the whole series by years shows that the rise of incidence of pain is steady and gradual throughout the menstrual histories studied. The rate increase over 8 years is less than three times the original value.

16. The incidence of disturbed general health and happiness also increases progressively with length of menstrual history.

17. Irregularity definitely decreases in incidence with increasing length of history.

18. The average duration of the period shows no tendency to rise or fall with increasing length of history.

Commentary.

In considering the results of the inquiry the London Association of the Medical Women's Federation desire to call attention to certain features of the questionaire which inevitably limited the scope of the inquiry and rendered the answers less informative than they could have wished. In the first place, it has been found impossible to elicit from the figures the average age of onset. This could only have been done by taking sample groups of girls and ascertaining which of them had begun to menstruate and which had not. The headmistresses considered that it would be injudicious to risk causing offence by questioning children who had not yet menstruated; hence in nearly all schools papers were only issued to girls known to have attained puberty. It is felt to be particularly unfortunate that no mention of *menorrhagia* was permitted on the questionaire, as many aspects of this condition call for further investigation. On *regularity* it was found difficult to get accurate answers in spite of explicit questions. The tendency was to express the intervals in weeks, although there was some doubt if this was strictly accurate. A very large number of girls kept no written record, but in comparison of the two groups there was less difference than might have been expected.

It will be noted that the degree and the duration of "pain" were not asked for. It is noteworthy, however, that only 61 stated that the pain was "bad" or "severe" or "much," and 700 explicitly stated that it was slight. It is remarkable to have ascertained that over 55 per cent. of schoolgirls have no pain or disability at all at a time when popular tradition pictures their lives as so profoundly affected by this physiological change. The apparently high percentage of pain should be read in connexion with the returns for absence. Experience teaches that if a girl has more than trivial or quickly passing pain she is not sent to school, yet the "absences" are extremely low and the habitual absences negligible. The whole picture presented suggests that the pain of menstruation is in the vast majority of cases slight and of very short duration and constitutes no serious interference with the girl's routine of life.

Some of the pain recorded occurred only "after" the period and in a small percentage "before, during, and after." There is much reason to suppose that such pain would not be truly of menstrual origin. There is a well-known tendency to connect any recurrent physical symptom in girls, especially abdominal pain, with this function, and most chronic appendices and obscure hepatic and digestive troubles get swept into the net.

From replies to Questions 8 and 10, the Commitee of Investigation received the definite impression that much of the discomfort complained of, and some of the disinclination to play games, was due to lack of appropriate toilet facilities and possibly of proper teaching in the hygiene of the period. The discomfort due to chafing may be just as severe a handicap on activity as actual dysmenorrhœa, but it is still true that at many playing fields and even in some schools no facilities for the necessary change are provided. There is no doubt that for this reason alone many girls refrain from active exercise during the period. A few mothers mentioned this difficulty specifically in returning the questionaires, and asked for improvements in the school arrangements. It would seem very desirable that any girl should be able to obtain a fresh towel and to dispose of a soiled one either at school or in the playing pavilion. Any traditional fear of washing should, of course, be removed if it still exists.

The question on exercise was not very happily worded, for unfortunately the questionaire did not

distinguish between free-standing and gymnastic exercises, although their effect on the menstruating girl is very different. Question 10 "Does she wish to (play games)? If not, what reason is given?" left room for an ambiguity not foreseen. Many papers answered "yes," but it appeared from Question 9 that the girl did not in fact play during the period! The reason why she did not was left obscure.

The committee would be glad to see the inquiry extended over the later years of adolescence and womanhood. It is important to ascertain, for example, what degrees of disability are present in girls at college and at work, what hygienic rules diminish such disability, and to what extent complete regularity of periods becomes established among normal women.

The members of the subcommittee responsible for this report are Dr. Christine Murrell (president), Prof. M. Lucas Keene, Dr. Lilian Jeffreys, Dr. Kate Platt, Dr. Ellen Pickard, and Dr. Letitia Fairfield (secretary).

MR. GANDHI AND "THE LANCET."

UNDER the heading of Notes from India in our issue of March 8th, our India correspondent said:

"Whatever political agitators may say, and in spite of the growth of medical education in India, that country will need British doctors for a long time to come. Even Mr. Gandhi (who was himself operated on by a British surgeon in the I.M.S.) would probably admit the truth of this statement."

According to the *Sind Medical Journal*, Mr. Gandhi has replied as follows in the columns of *Young India*:

"The insinuation made by the writer in THE LANCET is baseless and vicious. At the time the operation was performed I was certainly a prisoner, but I was given the choice of having my own surgeon to perform the operation. I did not distrust Col. Maddock, the British surgeon referred to, and the late Dr. Dalal and Dr. Jivaraj Mehta (my surgeon and physician respectively) not having arrived in time, the operation was performed by Col. Maddock, whose care and attention I have acknowledged more than once. I have never felt the dearth of Indian surgeons or physicians of the highest calibre. Indeed, I have sent several of my European friends to Indian surgeons and physicians, and they have derived full benefit from the skill of these Indian medical men. It is in military science alone, thanks to the British policy, that India perhaps stands in need of assistance from European instructors. But so far as I am aware, in every other department, if the British withdrew, India could be self-contained without the slightest difficulty, and that in spite of open or veiled obstruction from the ruling caste."

Our India correspondent writes: "Mr. Gandhi's statement is correct. He asked for an Indian surgeon in the first place. He was wired for but could not come in time."

TULARÆMIA IN THE LEMMING.

HITHERTO the lemming has been regarded mainly as a nuisance to farmers and a warning to the obstinate. Sweeping down in millions from the mountains to the farms surrounding the lakes and fjords, these fearless little black-and-tan rodents acknowledge no obstacle; when they meet a man, they express their opinion of him in terse squeaky barks instead of passing by on the other side in apologetic silence; and when they encounter a lake or fjord in their migrations, they swim it—or try to. The sequel is often the pollution of the Norwegian waterways with countless corpses. As Dr. T. Thjötta, of the Army Bacteriological Laboratory in Oslo, points out in *Tidsskrift for den Norske Laegeforening* for June 1st, the public in districts subject to lemming invasion has identified certain symptoms with this rodent, grouping them under the collective term "lemming disease." The reports of medical officers of health seem, indeed, to suggest that there are at least two diseases traceable to the lemming: a gastro-intestinal form caused by paratyphoid *coli* bacilli, and a glandular form. Thjötta has examined an example of the first form bacteriologically, but what is of more interest in connexion with the present world-wide study of tularæmia is his correlation of its manifestations with those of the glandular form of "lemming disease." They are, indeed, so like each other that, in his opinion, "one is fully warranted in identifying 'lemming fever' with tularæmia until the contrary has been proved." He has already demonstrated the existence of tularæmia in Norway among persons shooting hares or selling them in shops, and he has published 11 serologically proven cases. His first case was that of a medical man who, after shooting hares in the autumn of 1929, developed the ulcero-glandular form of the disease and was ill for months though still able to work. All, or nearly all, of the cases hitherto reported from Norway have been associated with hares, but as lice, flies, ticks, rats, and squirrels have been incriminated in one way or another in the propagation of this disease in other countries, it is probable that in Norway also its diagnosis in persons having no association with hares is only a matter of time. Dr. Thjötta's tentative inclusion of the lemming among the carriers of tularæmia will assuredly attract much material to his laboratory, and the forthcoming reports will be awaited with interest.

Births, Marriages, and Deaths

BIRTHS.

FOTHERGILL.—On June 22nd, at Ambleside, Westmorland, the wife of Dr. E. L. Fothergill, of a son.

MATTHEWS.—On June 23rd, at Newbridge-road, Bath, the wife of Dr. E. Russell Matthews, of a daughter.

SHARP.—On June 25th, at Welbeck-street, W., the wife of Dr. B. Buckley Sharp, of a son.

MAYBURY.—On June 6th, at Tulagi, British Solomon Islands, the wife of Lysander Montague Maybury, M.A., M.B., B.Chir., D.T.M. and H., of a son.

MARRIAGES.

ANDERSON—HAYES.—On June 26th, at the Church of Our Lady of Dolours, John Keith Anderson, M.B., Ch.B., to Geraldine Juliana Gregg Hayes, L.R.C.P. Lond., M.R.C.S. Eng.

CAUTLEY—MEDWIN.—On June 24th, at St. Benedict's Priory, Ealing, Ronald L. Cautley, L.D.S. R.C.S. Eng., to Ena Lillie, younger daughter of Mr. and Mrs. John Medwin, of Ealing.

DEWES—NEVILLE-ROLFE.—On June 25th, at Flax Bourton, Gordon Cripwell Dewes, M.D. Camb., M.R.C.P., to Ione, eldest daughter of Captain Herbert Neville-Rolfe, D.S.O., R.N., and Mrs. Rolfe.

DOCKRAY—SANDS.—On June 25th, at Kinross East Church of Scotland, Edgar Dockray, M.B., Cobham, Surrey, to Margaret Maud, only daughter of David Sands, Esq., Kinross, formerly of Curityba, Brazil.

GLYNN—GIBSON.—On June 28th, at All Saints', Ennismore-gardens, S.W., Dr. Noel Trelawney Glynn, M.R.C.P., to Dr. Christine Gibson, daughter of Mr. and Mrs. H. Y. Gibson, of Duddingston House, Sunbury-on-Thames.

MACVICKER—BULTEY.—On June 28th, at St. James's, Piccadilly, George Colin Churchill MacVicker, B.A., M.R.C.S., L.R.C.P., to Joan Eleanor, second daughter of the late Mr. and Mrs. Ayerst H. Bultey, of Hampstead.

DEATHS.

BERINGER.—On April 25th, at Kyoto, Japan, F. J. A. Beringer, M.R.C.S., L.R.C.P., aged 55, late Director of Medical and Sanitary Services, Sierra Leone.

GERVIS.—On June 30th, at Shepway, Seaford, Sussex, Charles Berkeley Gervis, M.D., M.R.C.S., L.R.C.P., aged 54.

PRANKERD.—On June 26th, at Hornsey-lane-gardens, Orlando Reeves Prankerd, M.D. Edin.

ROCKLIFFE.—On June 23rd, at Selioke, Hessle, Yorks, William Craven Rockliffe, M.A., M.D., aged 81.

SUCKLING.—On June 24th, at Wolverene, Cliftonville, Margate, John Jerome Suckling, M.B., B.S. Lond.

WILLIAMS.—On June 24th, at Caeronnen, Bangor, William Lloyd Williams, M.B., J.P., formerly of Llanberis, aged 75.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

DIPLOMA IN TROPICAL VETERINARY MEDICINE.—The University of Edinburgh and the Royal (Dick) Veterinary College, Edinburgh, have decided to institute in October, 1930, a course for a diploma in tropical veterinary medicine. The institution of this course follows upon the suggestion made by the Lovat Committee on the Colonial Veterinary Service that adequate post-graduate training in this subject should be provided.

ADDRESSES AND ORIGINAL ARTICLES

THE RESERVE FORCES OF THE KIDNEY.*

BY E. B. VERNEY, M.B. CAMB., F.R.C.P. LOND.,
PROFESSOR OF PHARMACOLOGY IN THE UNIVERSITY OF LONDON, AT UNIVERSITY COLLEGE.

WE may consider the capacity of the kidney to perform an increased amount of work as being determined by the quantity of renal tissue at rest at the time and by the magnitude of its response to any given stimulus. The former may be referred to as the structural, the latter as the functional reserve of the kidney. Both are doubtless closely interconnected, but for the purposes of this lecture it will be convenient to consider them separately.

The Structural Reserve.

Nearly one hundred years ago William Bowman published the results of his carefully conducted investigation "On the structure and use of the Malpighian bodies of the kidney, with observations on the circulation through that gland." He was led to conclude that

"all the blood of the renal artery (with the exception of a small quantity distributed to the capsule, surrounding fat, and the coats of the larger vessels) enters the capillary tufts of the Malpighian bodies; thence it passes into the capillary plexus surrounding the uriniferous tubes, and it finally leaves the organ through the branches of the renal vein. . . . With the inconsiderable exceptions just mentioned the terminal twigs of the artery correspond in number with the Malpighian bodies. . . . The blood leaving the Malpighian tufts is conveyed by their efferent vessels to the great renal reservoir, the capillary plexus surrounding the uriniferous tubes. . . . The vessels lie in the interstices of the tubes, and everywhere anastomose freely so that throughout the whole organ they constitute one continuous network lying on the outside of the tubes, in contact with the basement membrane."

Since the vessels bathing the tubules are capillary in character the capacity of one part of the vascular network to feed an adjacent part is extremely limited. The occurrence and character of infarcts in the kidney bear adequate testimony to the rigidity of this restriction in that they demonstrate the dependence of a tubule for its blood-supply on the patency of its respective glomerular tuft, or at least on the transmission of blood through those glomeruli which preside over tubules in its immediate neighbourhood. Bowman clearly recognised and described the repetitive character of the architecture of the kidney, and realised that the functional response of the kidney at any time was the integral of the responses of its individual units. The recent researches of H. F. Traut have shown that a human kidney contains approximately four and a half million such units. The normal man, then, possesses roughly ten million glomerulotubular units, each of which must be regarded as capable of furnishing its quotum of fully formed urine. The possibility that the structure as described by Bowman might form the basis for an alternation of function between the various parts of the kidney was realised by Hermann and given a concrete basis in fact by the beautiful experiments of Richards and his colleagues. They were able to observe directly in the frog's kidney an intermittence of glomerular circulation, an intermittence which was on the one hand unrelated to the heart beat, and on the other asynchronous in the group of glomeruli under observation. The number of units is so large that the possibility must be entertained of the kidney as a whole functioning efficiently under normal conditions when each unit comprising it works for a fraction only of its time. This alternation of activity and rest which the units of the kidney undergo may be looked upon as the concrete representation of its first line of defence against the inroads of disease, and of a part of its total capacity for dealing with an increased load of work. The mobilisation of this structural reserve was actually seen in operation after the intravenous injection of diuretic substances, such as urea, caffeine, and sodium sulphate, and following section of the sympathetic nerve-supply of the kidney. Is there any evidence that the units composing the mammalian kidney enjoy rest pauses of the existence of which direct proof is forthcoming in the case of the kidney of the frog?

EVIDENCE IN FAVOUR OF A STRUCTURAL RESERVE IN MAMMALS.

The evidence is indirect, and depends upon an appreciation of the mode of response of the mammalian kidney to an increase in the intensity of an applied stimulus.

The dependence of the kidney on an adequate blood pressure in order that its secretory activity may be initiated and maintained was demonstrated by Goll, a pupil of Ludwig, in 1854, and since that time much work has served to confirm the validity of his original observations. Changes in the pressure of blood-supply to the kidney, provided an adequate blood flow is maintained, are reflected in like changes in the rate of urine secretion, and these changes in rate are, as Ludwig pointed out, themselves accompanied by characteristic changes in the composition of the urine. As the rate increases the concentration of urea falls, and as a general rule we may say that increases in rate of urine flow are accompanied by an approach in the composition of the urine towards that of the blood plasma.

It might be expected, therefore, that any difference in the simultaneously observed rates of secretion by the two kidneys of an animal would be reflected in an accompanying difference in the chemical compositions of the urines, the higher rate showing a nearer approach towards, the lower a further recession from, the composition of the blood plasma. That such is usually the case with respect to urea was shown by Hermann in 1859. Hermann collected the urine from each ureter in the narcotised dog and was able to confirm the experience of Goll and Ludwig that the two kidneys commonly furnished unequal volumes of urine in the same interval of time. First one then the other secreted more rapidly, and the occurrence of this rhythm disproved the validity of any interpretation in terms of a difference in the structure of the two kidneys. The rhythm could manifestly receive a complete explanation in terms of an alternate waxing and waning of the pressure stimulus uniformly distributed throughout the kidney, were it not for the fact that the higher rate of flow was occasionally accompanied by a higher concentration of urea in the urine. This association led Hermann to postulate that an inequality in the simultaneously observed rates of urine secretion by the two kidneys might rest not only on a difference in the rates of secretion by each kidney as a whole, but also on a difference in the rates of secretion by different parts of the same kidney. He points out that if one assumes that the kidney of one side secretes throughout at a slow rate, whilst on the other side one part rests and the

* The Sydney Ringer Lecture delivered at University College Hospital Medical School, London, on March 17th, 1930.

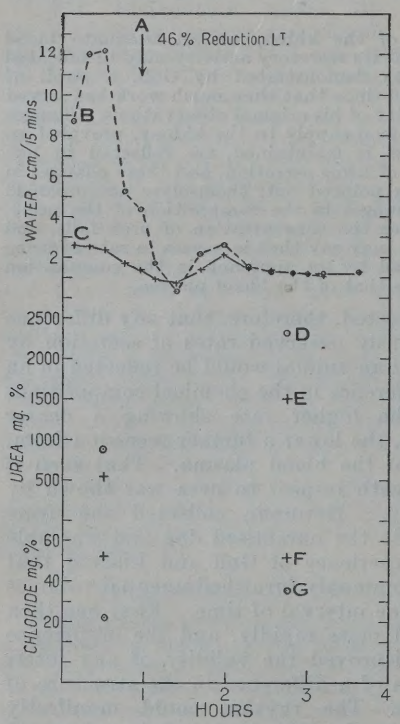
remainder secretes rapidly, the urine from the one kidney may be collected more rapidly in spite of its being more concentrated than that simultaneously collected from the other.

These observations of Hermann have been recently confirmed in part in the unanæsthetised dog by Miss L. M. Pickford and myself, and the possibility investigated of calling into activity renal units hitherto dormant.

At a preliminary operation under ether anæsthesia a fine silver cannula is implanted in the upper part of each ureter in such a manner that its upper end lies free in the renal pelvis. The lower end of this cannula is attached by a length of fine rubber tubing to a short glass cannula inserted into the lower end of the ureter and fixed in such a position that its tip protrudes into the cavity of the bladder. To this end of the glass cannula is attached a further length of rubber tubing, which in its turn is passed down the urethra to the exterior.

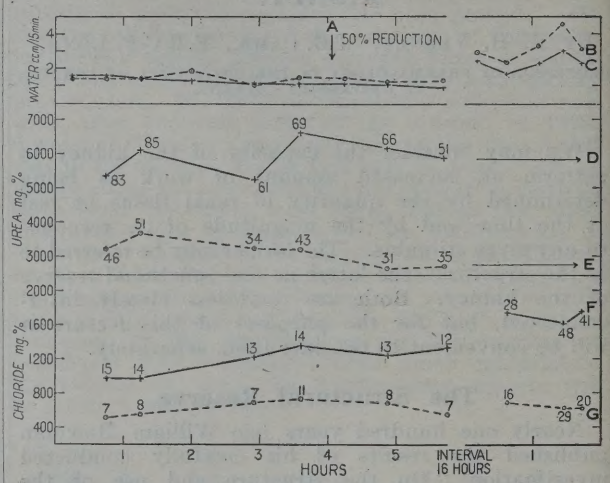
The secretion of one kidney may thus be collected separately from that of the other, and observations made thereon after the animal has recovered from the operation. It is found that under such circumstances the rates of secretion and the compositions of the urines are usually identical on the two sides. When the rates of flow are unequal the more slowly secreted urine has, as a rule, the higher content in urea. Occasionally, however, the reverse is seen, and in Fig. 1 are given the results of an experiment in which this phenomenon is exhibited. It will be observed that the rate of secretion by the left kidney is two to five times greater than that by the right, but that the urine from the left side contains not a lower but a higher percentage of urea than that from the right side. The simplest interpretation of the facts here depicted would appear to be that in the right kidney relatively few units were working at comparatively high pressure, whilst in the left kidney a very much larger number were engaged at a relatively low pressure. A large structural reserve on the right side was being maintained at the expense of an encroachment on the functional reserve of those units engaged in secreting urine. At the point A the circulation through 46 per cent. of the left kidney was suddenly arrested by occluding the posterior primary branch of the renal artery by a method which will be described in a moment. The rates of urine flow on the two sides were by this means brought to approximate equality but the sign of the difference in composition was maintained. The results of Hermann's work, confirmed by such an experiment as has just been described, must, I think, be interpreted as evidence that the number of active renal units in the one kidney, and their degree of activity at any one time, may be independent of the number of active units and the degree of activity of those in the other kidney.

FIG. 1.



B = rate of water elimination by the left kidney; C = that by the right kidney. D = concentration of urea in urine from left kidney; E = that in urine from right. F = concentration of chloride (as NaCl) in urine from right kidney; G = that in urine from left.

FIG. 2.



B = rate of water elimination by the left kidney; C = that by the right kidney. D = concentration of urea in urine from right kidney. E = that in urine from left. F = concentration of chloride (as NaCl) in urine from right kidney; G = that in urine from left. The figures on the urea and chloride graphs represent the amounts (in mgms.) of urea and of chloride (as NaCl) respectively, secreted in 15 minutes.

MOBILISATION OF THE STRUCTURAL RESERVE.

With such evidence before us of there being a varying amount of reserve tissue in the kidney, evidence direct in its nature in the case of the frog's kidney, indirect in the case of the mammal's, we may inquire whether a reduction in the amount of kidney substance is accompanied by an increase in the number of active units in the remaining parts of the kidney. An attempt has been made to answer this question, and although the experiments have as yet yielded results which are more equivocal than might be desired, yet they do point to there being, under certain as yet undefined circumstances, a calling into activity of dormant units in response to arrest of the circulation through a part of the kidney. The preparation used in these experiments is similar to that already described with the addition that means are afforded of ligating a branch of or the whole renal artery of the dog in the unanæsthetised state.

At the operation, during which the ureters are extended to the surface as already described, a fine Bowden cable is fixed to the posterior abdominal wall in such a position that its upper extremity lies behind the left kidney. The lower end of the Bowden tube is passed into the left Fallopian tube to reach the exterior through the uterus and vagina. A silk thread fixed at the upper end of the Bowden tube loops loosely around the renal artery or one of its branches, and passes to the exterior along the centre of the tube. The possibility is thus presented of arresting the blood flow through the renal artery or one of its branches by simple traction on the centre core of the Bowden tube. This can be done later without causing the least disturbance to the animal. The acute effects of this procedure on urinary secretion may thus be observed under environmental conditions and correspondences closely approaching the normal.

If, now, arrest of the circulation through a part of the kidney called into activity a number of units

which were previously dormant, we should expect a relative increase in the rate of urine flow from the non-infarcted region without there being any marked change in the composition of the urine. That such may indeed occur is indicated by the results of the experiment illustrated in Fig. 2. The observations were made four days after the operation, at a time when the animal was perfectly fit, as indicated by the excellence of its appetite and its freedom from fever. At A the posterior branch of the left renal artery was occluded. Post-mortem examination showed that about 40 per cent. of the kidney substance on the left side had been functionally excluded by ligation of the arterial branch. In spite of this, however, neither the rate nor the composition of the urine on the left or the right side was appreciably altered.

The determination, on the one hand, of the sequence of events involved in the production of this increase in the rate of secretion by the non-infarcted mass of kidney tissue, and on the other of the conditions under which it may be observed, must be left to further experimentation, but the interpretation of the results obtained would seem to lie in terms of a mobilisation of a greater or smaller part of the anatomical reserves of the affected kidney.

The Functional Reserves.

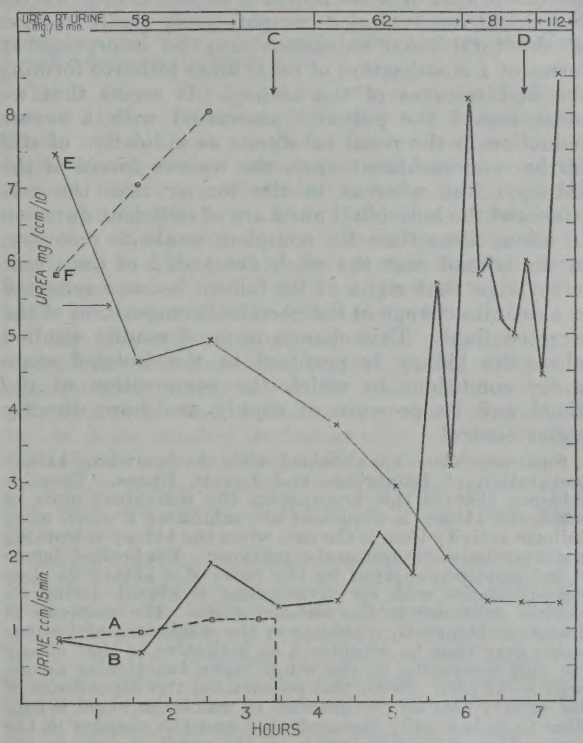
EFFECTS OF REMOVAL OF LARGE AMOUNTS OF RENAL TISSUE IN THE DOG.

So far we have considered the response of the kidney to the functional removal of a relatively small fraction of the total renal substance. We must now attempt to determine whether and, if so, how, the kidney adapts to such a diminution in the amount of tissue that the mobilisation of all the remaining units is by itself unable to cope with the work which it is called upon to perform. In this connexion I should like first of all to refer to some of the fundamental observations which were made by Sir John Rose Bradford in his experimental inquiry into the effects of reducing, by surgical means, the amount of kidney tissue in the dog. It was shown that even when the amount removed was as small as one-eighth to one-quarter of the total, the output of urine was usually increased, but that the removal of larger amounts, ranging up to two-thirds of the total, was followed by a much greater increase in the amount of urinary water.

This increase was not only considerable but also persistent, having been observed, for example, 15 months after the operation. There was no increase in the amount of urea excreted, but a rise was observed in the nitrogenous extractives of the blood and tissues. Such animals were unable to excrete a concentrated urine, and if very large amounts of nitrogenous food were given the urea formed was readily excreted, but only at the expense of a still further increase in the volume of urine. To quote from an original paper: "The cause of the increased excretion of urinary water when the amount of available kidney is thus reduced is by no means clear; it is, however, not associated, as far as my observations have gone, with any very great increase in the general blood pressure." The possibility was suggested, however, that the increase in urea in the blood was the cause of the hydruria.

Using the technique already described, Miss Pickford and I have made a few observations on the unanæsthetised dog to determine whether the polyuria obtained in the experiments of Rose Bradford was reproducible under the somewhat different conditions of our own. In Fig. 3 are given the results of an experiment in which after three and a half hours preliminary observation the left renal artery was suddenly occluded in the unanæsthetised animal. Within the next hour an increase in the rate of urine flow from the right kidney asserts itself, and mounts within the following two hours to a figure nearly three times as great as the sum of the rates of flow from the two kidneys immediately before the circulatory arrest on the left side. The percentage of urea, as will be seen, underwent a profound fall; the amount secreted per unit of time by the right kidney gradually increased towards, but in the interval during which the observations were made did not reach, the rate of urea secretion by the two kidneys in the early part of the experiment. It is probable, therefore, that the urea content of the blood of this animal during the observed polyuric response was

FIG. 3.



A = rate of water elimination by the left kidney; B = that by the right. C = time of ligation of left renal artery. At D 0·5 unit pituitary extract was injected subcutaneously. E = concentration of urea in urine from right kidney; F = that in urine from left.

higher than that before the total renal substance was functionally reduced by ligation of the left renal artery. The results of this experiment would appear to be closely comparable with those described by Rose Bradford, and with those of the experiments of Nature in which the amount of functioning tissue is gradually reduced by the inroads of disease. Here we are observing the gradual development and the initial stages of that polyuria which is the outstanding result of the other two types of experiment. The immediate ætiology of this response is obscure, but there are a few points in this connexion to which attention may be directed. First, the increased urinary flow is not determined by an increased water intake. In the experiment under discussion the animal drank no water during the whole period of observation. And we may correlate with this fact the observation that the increased output of water was not inhibited by the subcutaneous injection of pituitary extract. Indeed, it has been our experience that pituitary extract increases rather than diminishes the polyuric response to experimental reduction in the total renal substance. This absence of an inhibitory

response to pituitary extract is another sign of semblance between this polyuria and that found in certain types of cirrhosis of the kidney. Secondly, it is impossible to say at present whether the polyuria which we are considering is immediately dependent on a maintained change in the composition of the blood supplied to the remaining fragment of renal tissue, or whether it is in part or in whole the result of an interference with a correlation between the two kidneys through the intermediation of the sympathetic nerves. The type of response, however, is similar to that observed when the kidney is subjected to a large increase in the pressure of its arterial blood-supply. We have seen that the response to an increased load of work imposed on the kidney by the functional removal of a comparatively small fraction of the total renal substance may be interpreted in terms of a mobilisation of renal units hitherto forming the first reserves of the kidney. It seems that we must regard the polyuria associated with a severe reduction in the renal substance as indicative of still further encroachment upon the reserve forces of the kidney. But whereas in the former case the rest pauses of the individual units are of sufficient duration to allow them time for complete anabolic recovery, in the second case the work demanded of each unit is so large that signs of its failure become reflected in a definite change in the chemical composition of the secreted fluid. This change is most readily studied when the kidney is perfused in the isolated state under conditions in which the composition of the blood and its pressure of supply are more directly under control.

Such conditions are obtained with the heart-lung-kidney preparation of Bainbridge and Lovatt Evans. There is evidence that in this preparation the individual units of which the kidney is composed are exhibiting a much more uniform activity than is the case when the kidney is working under normal environmental conditions. The limited degree of independence enjoyed by the units of a kidney in close correspondence with its environment is absent during its rootless existence in the isolated state. The response of the whole kidney to a change in the conditions of its perfusion may thus be considered as indicative of that of any one unit composing it, the whole organ functioning as one large renal unit. With this preparation the dependence of the urinary flow on the pressure at which the blood is supplied to it is readily demonstrated and the changes in the composition of the urine when, as the result of a rise in the perfusion pressure, the rate of secretion is increased, determined with ease. Any increase in the pressure stimulus is accompanied by an approach in the composition of the urine to that of the blood plasma, an approach which is to be regarded as a sign of failure to cope adequately with the demand for increased work. And there is evidence that the increment of urine flow produced by an increase in the pressure stimulus is not diminished by the addition of pituitary extract to the circulating blood.

There seems, then, to be sufficient evidence for the tentative association of the polyuria following experimental reduction in the renal substance with a pressure diuresis as seen in the isolated kidney, and for regarding both conditions as the inevitable result of an increased effectiveness of the pressure stimulus. Whether this is tantamount to saying that both are accompanied by an increased rate of filtration through the Malpighian tufts is debatable. All one wishes to emphasise here is the supreme importance of the pressure stimulus, and to point to the changes observed to follow reduction of the renal substance by the experiments of surgery or possibly of disease as being explicable in terms of an increase in this stimulus.

EFFECTS OF LIGATION OF A PRIMARY ARTERIAL BRANCH IN THE ISOLATED KIDNEY.

I should like at this stage to refer to a phenomenon exhibited by the isolated kidney in response to ligation of a primary arterial branch, since it seems possible that it may have some bearing on the polyuria which we are led to regard as the sign of a severe encroachment on the reserves of the kidney.

When the two kidneys of a dog are perfused side by side by means of a heart-lung-preparation the rate and composition of the urine secreted by the one are commonly equal to those of the urine secreted by the other. Moreover, they react by quantitatively equivalent responses to any common change in the conditions of their perfusion. It would be expected from purely anatomical considerations that the ligation of a primary branch of one renal artery would be accompanied by a diminution in blood flow and in urine flow percentually equivalent to the ratio between the infarcted tissue and the whole kidney. If 50 per cent. of the kidney were put out of commission by such means we should expect tha blood flow and the urine flow to suffer a similar diminution, the composition of the urine remaining unchanged when compared with that secreted by the other kidney, which is functioning throughout as a simultaneous control. Experimentally it is found that there is, indeed, a marked fall in the blood flow through the kidney, a fall, moreover, which corresponds accurately with the diminution in the amount of functioning tissue. The urine flow, however, shows no comparable diminution; indeed, quite commonly an absolute increase in its rate is encountered, an increase, moreover, which is immediate in its onset and often progressing as the experiment proceeds.

On arresting the circulation, then, through a part of one kidney perfused in the isolated state, the remaining part, without a moment's hesitation, secretes much more rapidly than before. Analysis of the urine shows that the percentage of urea has suffered a profound fall, whilst the chloride percentage remains steady or, as is commonly the case, shows an actual increase towards the plasma level.

The sequence of events through which the one part of the kidney becomes cognisant of the infarction of the other and immediately responds by secreting urine at a faster rate is by no means clear as yet. It must be a strictly localised one, since no polyuric response is given by the other kidney which is being perfused simultaneously with the same blood. We are able, however, to form a clear idea of the nature of the stimulus to which the non-infarcted region becomes subjected. We mentioned earlier the effects on the rate and composition of the urine of an increase in the pressure at which the blood was supplied to the isolated kidney, and we have just seen the effects of circulatory arrest in the one part of the kidney on the rate and composition of the urine secreted by the other part. The effects are qualitatively and, as has recently been shown, quantitatively identical. The reduced kidney thus responds at constant blood pressure exactly as though it were being subjected to an increase in perfusion pressure, the resultant polyuria being indicative of a dwindling of the functional reserves.

The intimate changes involved in the phenomena which we have so far discussed—viz., the mobilisation of dormant units with or without the subjection of the kidney to an intrinsically developed increase in the pressure stimulus as the result of reducing by experimental means the total mass of renal tissue—are obscure, and the phenomena themselves are of interest in pathology only in so far as they afford a possible parallel with those occurring during, and as the result of, the more gradual reduction which occurs in disease.

MAGNITUDE OF THE PRESSURE STIMULUS.

The physiological experiments to which attention has been directed emphasise the continuous correlation which must exist between the work required of the kidney and the magnitude of the pressure stimulus. On the other hand, we are confronted in health with a maintained constancy in the arterial blood pressure. The peculiar vascular arrangements in the kidney,

however, allow of the possibility of changes in the intraglomerular capillary pressure within wide limits, irrespective of any change in the general arterial blood pressure. Dilatation of the vas afferens with respect to the vas efferens will be accompanied by a rise, dilatation of the vas efferens with respect to the vas afferens by a fall in intraglomerular pressure. The functional reserve of any one renal unit—that is, its capability to perform an increased amount of work—may be limited either by a fall in the magnitude of the pressure stimulus or by a diminution in its effectiveness owing to a fall in the responsiveness of the tubular cells. The stimulus itself may be too small or its translation into effectiveness may be impeded by a diminution in the capacity of the tubule, under an adequate stimulus, to perform work. There are, then, two factors which must be considered in any attempt to assess the functional reserves of the kidney—namely, the magnitude of the pressure stimulus and what may be termed the "tone" of the tubular epithelium. To the latter we shall refer later. Up to the present we have pointed to the increased rate of urine flow which is seen to follow experimental reduction in the renal substance as being explicable in terms of an increase in the pressure stimulus. The degree to which this stimulus can undergo an intrinsic rise is obviously limited by the level of the general arterial blood pressure, and it would be of extreme interest to attempt to discover whether a diminution in the renal tissue to such an extent that the maximal stimulus to the remainder was incapable of producing an adequate response, would be followed by a rise in the general blood pressure.

The existence of a physiological mechanism which might effectively be brought into play in this connexion was demonstrated by Rose Bradford during investigations designed to supply the physiological counterpart of Gaskell's anatomical researches on the involuntary nervous system. It was shown that "stimulation of the anterior roots or of the entire nerve after division of the posterior root . . . was followed by contraction of the kidney and a rise of general blood pressure when any nerve from the sixth dorsal to the second lumbar inclusive was the one selected." Although the excitation of all these nerves produced contraction of the kidney and a rise in blood pressure, yet on the whole stimulation of the lower nerves was more efficacious than stimulation of the upper, the greatest contraction of the kidney being caused by stimulation of the eleventh, twelfth, and thirteenth dorsal nerves. Thus the area from which the kidney vessels are supplied is a very extensive one, and, as was pointed out, it was apparently coextensive with that supplying the abdominal vessels.

It was now found that when such a nerve as the thirteenth dorsal, which with quick rates of stimulation always gave a renal contraction and a rise of general blood pressure, was excited by means of slow rhythmic break shocks of one or two per second, the kidney underwent marked expansion and no change in blood pressure occurred. This true active dilatation of the kidney was only to be obtained by the stimulation of such a comparatively restricted series of nerves as the eleventh, twelfth, and thirteenth dorsal, the same series as that from which the most marked renal vasoconstriction was observed when high rates of stimulation were employed. So far, then, the existence of efferent vasodilator as well as vasoconstrictor nerves to the kidney had been clearly demonstrated, the nerves leaving the cord in the anterior roots of the lower thoracic nerves, passing thence to the splanchnic and so to the renal plexus.

The reflex phenomena of the renal vessels were next investigated, and it was shown that by reflex excitation, be it from the central end of the sciatic or from the central end of an intercostal nerve, it was more common to obtain contraction than expansion of the kidney, but that expansion was frequently obtained by the excitation of the posterior root of a nerve belonging to what may be called the renal area—i.e., the eleventh, twelfth, and thirteenth thoracic.

To quote from an original paper: "If a posterior root below the third lumbar nerve be excited, the rise of blood pressure is similar to that seen on excitation of the great sciatic; if, however, the central end of one of the upper lumbar or lower dorsal posterior roots be excited the rise of blood pressure is far greater in amount and more sudden in its onset; in fact, the effect is quite different from that seen with the lower roots. The anterior roots of these nerves contain, as we have seen, the vasoconstrictor fibres distributed to the vessels of the viscera, and these observations tend to show that these posterior roots also contain special afferent fibres capable of affecting the vasomotor system to a far greater extent than the ordinary afferent fibres seen in sensory nerves. In other words, this great and sudden effect in the blood pressure would tend to show that some posterior roots contain afferent fibres derived probably from the viscera and from the kidney amongst the viscera. The fact that there are such nerves distributed to the kidney and that the excitation of their central ends is capable of causing a very great effect on the vessels of the body generally, is also a fact that may have some bearing on the production of high tension in certain renal diseases. The other point about these afferent visceral fibres is that although their excitation causes a rise of blood pressure with general constriction, there is a local dilatation of the kidney—in fact, this is the only method by which, experimentally, any very considerable dilatation of the renal blood-vessels can be produced."

There is, so far as I am aware, no evidence in favour of the involvement of these reflex phenomena of the renal blood-vessels in the production of the high blood pressure associated with cirrhosis of the kidney, but it is nevertheless a tempting hypothesis to endow the kidney, derived from so extensive a number of segments, with the ultimate power of initiating a reflex rise in the general blood pressure and so of procuring for itself an increase in just that stimulus upon which its activity depends.

With the approach of the blood pressure to its upper limit the functional reserve, in the absence of hypertrophy, which as Rose Bradford showed, in response to removal of one kidney was inappreciable in old dogs, reaches its lowest ebb. A still further diminution in the amount of functioning tissue can now only remain compatible with life in so far as the excretory work of the kidney falls pari passu with it.

Before turning attention to the "tone" of the tubular epithelium as a factor in the functional reserves of the kidney it may be profitable to consider the possibility of renal failure being due essentially to the pressure stimulus being below an adequate level. In experiments with the heart-lung-kidney preparation it has been observed by Dr. F. R. Winton and myself that abnormally large rates of blood flow through the kidney tend to be accompanied by abnormally small productions of urine. One pictures in these cases so large a diminution in the tone of the glomerular vessels that an effective stimulus is hardly brought into being. The renal failure is to be regarded as due to lack of stimulus rather than to any inherent incapacity on the part of the tubule cells. The fall in the resistance of the glomerular bed must be reflected in a rise in the capillary pressure in the intertubular vascular network. Is it possible that such a condition may have some bearing on the oliguria of nephrosis? An observation by Dr. Winton on the isolated kidney of the dog may be not without interest and significance in this connexion. When the two kidneys of a dog are perfused with blood of the same composition by connecting them to a heart-lung preparation, the rate of urine flow from the one may be maintained equal to that from the other by appropriate variations in the perfusion pressure, in the ureter pressure, or in the venous pressure. A low perfusion pressure and normal ureter and venous pressures on the one side may be counterbalanced by a high perfusion pressure and high ureter or venous pressure on the other. But whereas in the former case—that is, when the two kidneys are secreting at equal rates, the one being under the influence of a low blood pressure, the

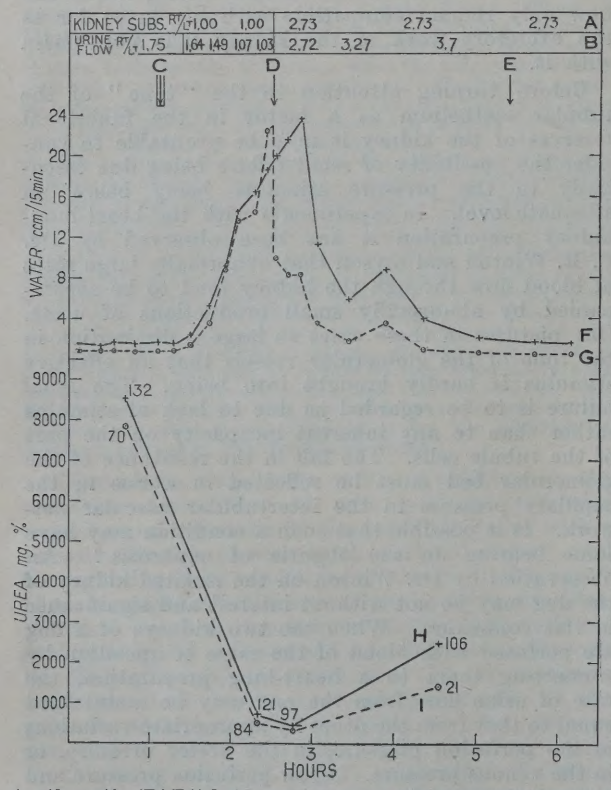
other of a high arterial pressure and high ureter pressure—the compositions of the two urines are, as far as has been determined, identical, in the latter case, that is, when a rise in venous pressure is substituted for a rise in ureter pressure, the equality of chemical composition is maintained with the important exception that protein makes its appearance in the urine. And over short periods of time the changes responsible for its appearance are completely reversible. Gross alterations, then, of the mechanical conditions under which the kidney is working do not influence the fundamental processes involved in the preparation of the urine, the non-colloidal composition of this being a function solely of the rate at which it appears. And the appearance of protein is not incompatible with the sustained integrity of these fundamental processes. A fall in the tone of the glomerular vessels with a consequent rise in the intertubular capillary pressure may conceivably be a factor in initiating the oliguria and proteinuria of that collection of signs which we associate in the term nephrosis.

"TONE" OF THE SECRETORY EPITHELIUM.

Up to the present we have considered the responses of the kidney to the putting out of commission of a portion of its substance, and we have seen that these responses are possibly explicable in terms of an increased pressure stimulus to the remainder. The diuretic response, then, must be regarded as being essentially reversible and truly physiological in its nature. The increased urine production by the remaining units with their partial failure as manifested by an approach in the composition of the urine to that of the plasma, may be compared with the physiological and reversible dilatation of the heart which occurs during exercise. And just as a pathological impairment in the capacity of heart muscle to perform a given amount of work is reflected in a dilatation of the heart more or less permanent in its nature, so in the case of the kidney a pathological impairment in the capacity of the tubular epithelium to perform work under an otherwise adequate stimulus is reflected in an approach in the composition of the urine to that of the plasma, a diuresis more or less permanent in its nature. Physiological dilatation of the heart and physiological diuresis are to be regarded as due primarily to an increased stimulus, pathological dilatation of the heart and pathological diuresis to a diminished efficiency of the heart muscle and tubular epithelium respectively. Arguing from analogy we should expect that for a given rate of urine production by renal units working under these two conditions there would be a wider divergence in the chemical work performed than in the oxygen consumed by them. The "tone" of the one is higher than the "tone" of the other. And it would appear that the responses of one part of the tubular epithelium to changes in the composition of the blood are not affected by the functional removal of the other part. The following two experiments demonstrate this when the applied stimuli are respectively the giving of water by the mouth and of urea intravenously.

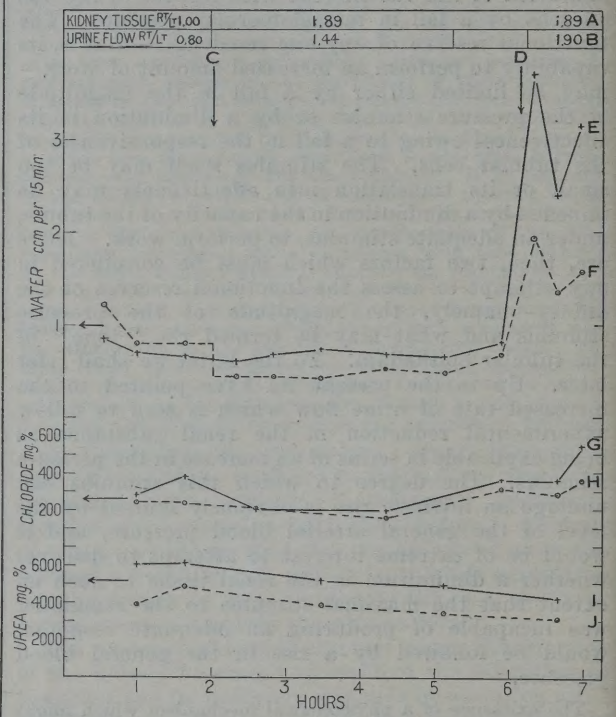
In the experiment illustrated in Fig. 4 it will be seen that the right kidney was secreting more rapidly than the left—

FIG. 4.



A = the ratio (Rt/Lt) between the amounts of functioning renal tissue in the two kidneys. B = the ratio (Rt/Lt) between the rates of urine secretion by the two kidneys. C = time of administration of 250 c.cm. water by stomach-tube. D = time of ligation of posterior branch of left renal artery. F = rate of urine flow from right kidney; G = that from left. H = concentration of urea in urine from right kidney; I = that in urine from left. The figures on the urea graphs have the same significance as in Fig. 2 (q.v.).

FIG. 5.



A, B have same significance as in Fig. 5 q.v. C = time of ligation of posterior branch of left renal artery. D = time of injection of 2 g. urea intravenously. E = rate of water elimination by right kidney; F = that by left. G = concentration of chloride (as NaCl) in urine from right kidney; H = that in urine from left kidney. I = concentration of urea in urine from right kidney; J = that in urine from left kidney.

namely, one and three quarter times. During the interval marked C 250 c.cm. of warm tap water were given to the dog through a stomach-tube. As the polyuria develops it will be observed that the ratio between the right and left rates of urine flow gradually approaches unity. At D 64 per cent. of the left renal substance was functionally removed by ligating the posterior branch of the left renal artery by the method already described. The urine flow on the left side falls in the same proportion, and as the water diuresis passes away the ratio between the right and left rates of urine flow per unit of kidney substance increases towards the value it held before the giving of the water. It would, of course, be of great theoretical interest and importance to know how the rates of blood flow through the two kidneys varied during such an experiment as this, but such information is not forthcoming.

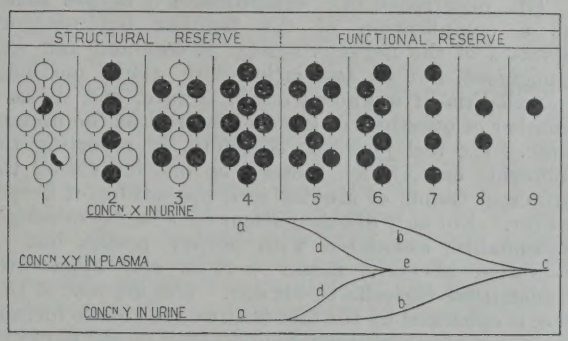
In Fig. 5 we see the results of an experiment in which urea was injected intravenously some time after part of the left kidney had been put out of commission. Ligation of the posterior branch of the left renal artery at C, thereby arresting the circulation through 47 per cent. of the kidney, gave in this experiment an almost proportional drop in urine flow as is seen from the constancy of the relation between the two ratios given at the head of the figure. At D 2 g. of urea in 10 c.cm. Sydney Ringer's fluid were injected intravenously. As the result of this the rates of urine flow now became directly proportional to the masses of tissue functioning in the right and left kidney, the original inequality in these ratios having disappeared.

Again, it would seem from studies on the isolated kidney that the relative or absolute increase in urine flow which we have described as resulting from ligation of a primary branch of the renal artery is itself unaffected by the addition of pituitary extract to the blood. The inhibition of the rate of urine flow which follows the addition of this extract is probably directly proportional to the amount of tissue functioning and not to the rate of urine elimination. A physiological diuresis brought into play through an increase in the pressure stimulus has, then, possibly very little or even no influence on the responses of the tubule cells to changes in the composition of the blood bathing them. A pathological diuresis, however, is, as we know, often accompanied by a profound diminution in these responses, the fall in the tone of the tubular epithelium being reflected not only in an increased flow of urine but also in a lack of correspondence between this epithelium and its environment, both of which are signs of a fallen reserve.

How far, if at all, the effects of this fall in the tone of the tubular epithelium which we conceive to be present in nephritis associated with polyuria may be comparable with the approach in the composition of the urine towards that of the plasma which occurs when the oxygen-supply to the kidney is experimentally reduced, or when the organ is subjected to small concentrations of cyanide, we cannot say. Prolonged constriction of the vasa efferentia might conceivably be an ætiological factor in its production, the polyuria being the summated result of the rise in intraglomerular pressure and reduced oxygen-supply to the tubules. And whether such a change varying in its intensity and duration throughout the multitude of glomerulotubular units could itself produce the functional derangements found in disease is a problem which only research in the future can show.

I have attempted in Fig. 6 to illustrate the calling into play and the progressive diminution in the reserve forces to which attention has been directed in this paper. In the column marked 2 are represented ten glomerulotubular units, four being active and six inactive. The term inactive is used in the sense that no urine is being secreted by this unit and not in the sense that no blood is flowing through its glomerulus. An increase in the work demanded of the kidney or a diminution in the mass of renal tissue is followed by an increased density of active unit in the functioning tissue, this increased density being represented in columns 3 and 4, and, as shown, reaching saturation in this last stage. During this progressive mobilisation of the structural reserves the composition of the urine would undergo essentially no very great change, as is indicated in the figure. A further increase in the work demanded of the kidney, or a further diminution in the mass of functioning tissue, can now be accomplished only through an incursion into the functional reserves,

FIG. 6.



For description see text.

the work done by each unit being greater than before. This is accomplished apparently by a rise in the magnitude of the pressure stimulus, and if the efficiency of this increment of work were sufficiently high the composition of the urine would remain still essentially unchanged. This state of affairs is represented in stage 5. A further reduction in the parenchyma of the kidney raises the pressure stimulus to the remainder still higher and secretion by each unit is now so rapid that the composition of the urine turns towards that of the plasma. This movement in composition towards the plasma will occur early or late according to the degree of tone of the tubular epithelium. Whereas in experimental reduction of the renal substance the mobilisation of the structural and functional reserves will be reflected in a late approach in the composition of the urine towards that of the plasma, in pathological reduction the mobilisation will be reflected in an early approach. The relative times of this approach are represented in the figure by the curves *a*, *b*, *c*, and *a*, *d*, *e*, respectively.

In the column marked 1 is depicted the state in the isolated kidney when the tone of the glomerular vessels is abnormally low, a state which, as previously suggested, may have some bearing on the condition of the vascular bed in nephrosis.

A BIRMINGHAM CONVALESCENT HOME.—The Birmingham Hospital Saturday Fund has purchased a site for a new convalescent home for women near Weston-super-Mare. At present 400 women are awaiting their turn to go to the two existing homes, some of whom cannot be accepted for two months. The new building will contain 100 beds.

A HOSPITAL MOTOR SERVICE.—The Merseyside Hospitals Council is organising a night transport service for taking relatives and blood transfusionists to the Liverpool hospitals in cases of urgency. Motorists who are on the telephone are being asked to hold themselves in readiness, each for one month in the year, to be rung up at any time during the night. Last year 100 transfusions were performed at the Liverpool hospitals, and some 1500 patients became dangerously ill during the hours when ordinary transport is not available.

ACUTE MENINGO-ENCEPHALITIS ASSOCIATED WITH HERPES ZOSTER.

A FATAL CASE.

BY C. I. SCHIFF, M.R.C.S. ENG.,

AND

W. RUSSELL BRAIN, D.M. OXF., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO LONDON HOSPITAL, AND HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE.

THE occurrence of "symptomatic" herpes zoster as a complication of the familiar inflammatory diseases of the nervous system is common and well recognised, but its association with acute meningo-encephalitis of unknown origin is rare, and raises a number of questions of unusual interest at the present time. We feel justified, therefore, in reporting the following case, which focuses in one individual the principal trends of inquiry into the nature of herpes zoster. Not only did the patient die of acute meningo-encephalitis associated with herpes zoster, but he exhibited aberrant zoster vesicles and apparently transmitted varicella to his son. The interest of this case is enhanced by the fact that we are able to include the result of complement-fixation tests on the patient's cerebro-spinal fluid carried out by Dr. S. P. Bedson and Dr. J. O. W. Bland.

Report of a Case.

A. B., a Hebrew, aged 67, was a corpulent man who had previously enjoyed good health. On August 10th, 1929, he began to complain of headache. Two days later he developed severe pain over the right lower jaw and half way down the right side of the neck. On August 14th a typical herpetic rash with large vesicles appeared in the painful area. Vesicles were present on the right side over the lower jaw, the upper half of the neck, the auricle, and the occipital region of the scalp. His temperature and pulse were normal. The patient now became drowsy and mentally confused. He was disorientated, and at times struggled to get out of bed. During the following two days the rash became pustular, and a similar pustule appeared on the abdominal wall.

On August 18th he was drowsy, and when roused to answer questions he was confused and disorientated. There was moderate cervical rigidity. The fundi were normal, and the pupils reacted briskly to light and on accommodation. There was bilateral ptosis and weakness of conjugate ocular deviation to the right. Otherwise the ocular movements were full, and squint and nystagmus were absent. There was slight weakness of the lower part of the face on the right side, and the tongue deviated to the right on protrusion. There was slight weakness of the right upper limb, but in the other limbs power was normal and there was no incoördination. The tendon jerks in the upper limbs were brisker on the right side than on the left. The knee- and ankle-jerks and the abdominal reflexes were not elicited, and the plantar reflexes were flexor. The only sensory abnormality was a zone of hyperalgesia corresponding to the cutaneous distribution of the second cervical spinal segment on the right side. There was no sphincter disturbance. Kernig's sign was absent. There were signs of bronchitis.

On August 18th the patient was admitted to the London Hospital, and on the 19th lumbar puncture was performed. The spinal fluid appeared to be under increased pressure, and 32 c.cm. were withdrawn. There were 120 mononuclear cells per c.mm.; protein, 0·06 per cent.; chlorides, 0·73 per cent. The fluid was sterile on culture and the Wassermann reaction was negative.

The patient remained in the London Hospital for ten days. During this time five new pustules appeared, widely scattered, on his back, and a purpuric rash on both knees. At first noisy and restless, he gradually lapsed into coma, but developed no fresh signs of involvement of the nervous system. His temperature did not rise above 99·4° F., nor his pulse above 100. Signs of broncho-pneumonia appeared and, at the request of his friends, on August 28th he returned home where he died on the 31st. There was no autopsy.

Two or three days before the patient's death his son, aged 32, who did not live in the same house but was in frequent contact with his father, developed a severe attack of varicella. His temperature reached 103° F., and he was acutely ill, but the attack subsided without any complications.

COMPLEMENT-FIXATION TESTS.

Bedson and Bland [1] have reported the results of complement-fixation tests in which the cerebro-spinal fluid of our patient was used as an antigen against the blood sera of two patients convalescent from herpes zoster and two normal sera. They first showed that fixation of complement occurred when three zoster convalescent sera were put up against two zoster vesicle fluids as antigens, while two normal sera gave negative results. Two of the convalescent sera gave fixation also with a third zoster vesicle fluid. These two sera were then used with the spinal fluid from our patient and with that from a case of encephalitis complicating diphtheria.

"The two zoster convalescent sera, 'X' and 'Y,' both gave fixation—weakly positive it is true—with the zoster encephalitis C.S.F., but no fixation with the other specimen. The two normal sera failed to give fixation with either. This finding appears to us significant, and suggests the possibility of using the test in the elucidation of the ætiology of encephalomyelitis." (Bedson and Bland.)

Other Recorded Cases.

Chauffard and Froin [2] were among the first to draw attention to the evidence for the occurrence of meningitis in cases of herpes zoster. They attributed the lymphocytosis in the spinal fluid in a case of ophthalmic zoster to an extension to the arachnoid of the inflammation arising in the gasserian ganglion. In 1907 Chauffard and Rendu [3] described another case of ophthalmic zoster in which the clinical features of meningitis, headache, cervical rigidity, and bradycardia were also present. They described the condition as "méningite zonateuse," and alluded to a case of thoracico-abdominal zoster in which Kernig's sign was present. Proust [10] reviewed the question of "la réaction méningée" in ophthalmic zoster. Souques [13] described a case of encephalitis lethargica in which herpes zoster developed eight months after the onset of the illness. Renon and Blamoutier [12] reported a case of anal zoster preceded by meningeal symptoms in the sacral region. Netter, who has made a special study of herpes zoster, reported a case of zoster associated with encephalitis in 1920[7] and had collected four further cases in 1922.[8] Netter's case 1 was a man of 33 who, nine days after the onset of intercostal zoster, developed myoclonus of the muscles of the abdominal wall, lumbar region, and buttocks. This symptom disappeared in a fortnight. A diagnosis of the myoclonic form of encephalitis lethargica was made, although it was admitted that the patient exhibited neither somnolence nor ocular symptoms. In case 2, a child, myoclonus of the upper limbs, cervical rigidity and slight unilateral ptosis coincided with an eruption of zoster on the right side of the chest and the proximal part of the right upper limb. Recovery occurred in a fortnight. Case 3 is briefly reported as encephalitis associated with ophthalmic zoster. Case 4 is that reported by Souques and already described. Case 5 was a girl of eight who became acutely ill with epileptiform convulsions, stupor, blindness, right hemiplegia and aphasia, cervical rigidity and Kernig's sign. The cerebro-spinal fluid was normal. This child developed herpes zoster on the right buttock 12 days after the onset of her illness. The patient made a partial recovery but died six months later of streptococcal meningitis. Her original illness was diagnosed as encephalitis lethargica. It is interesting that another patient in the same ward developed varicella 12 days after the outbreak of herpes zoster.

Tilney and Howe [15] described a case of encephalitis lethargica, characterised by weakness and lethargy blurred vision and diplopia, in which, three weeks after the onset, an atypical herpetiform eruption developed in the distribution of the left trigeminal nerve. Madsen [6] described the supervention of intercostal zoster five months after the onset of encephalitis lethargica.

Ramond [11] quoted two cases of meningitis complicating zoster in addition to those reported by Chauffard. Eschbach described a severe generalised meningitis developing on the sixth day after the appearance of thoracic zoster. Sicard reported a similar occurrence after ophthalmic zoster. Thalhimer [14] described a fatal case which bears some resemblance to our own and in which autopsy was obtained. His patient, a woman of 72, developed zoster in the right cervical region from the hair line to the clavicle. She died six weeks after the onset, having been drowsy for one week before death, but having shown no abnormal physical signs in the nervous system. Histological examination revealed perivascular infiltration of the nervous system with round cells and similar infiltration of the pia mater from the cervical cord up to the internal capsule. Gundersen [4] described a man aged 53 in whom herpes zoster in the lumbar region was associated with a generalised varicellar rash, paroxysmal hiccup, somnolence, cervical rigidity, myoclonia, athetosis, general paræsthesiæ, and parotitis.

Nature of the Association.

Clinical observation early divided cases of herpes zoster into two groups, "symptomatic" and "idiopathic." In the former the zoster arose subsequently to an injury, infection, or intoxication. In this group were placed the cases of zoster complicating spinal injury and tumour, syphilis of the nervous system, meningococcal meningitis, carbon monoxide poisoning and the therapeutic use of arsenic and bismuth. In "idiopathic" zoster no such predisposing cause could be found. This distinction between symptomatic and idiopathic zoster remains clinically important, but recent investigations have shown that there is no essential difference between the two conditions.[9] In both cases the histological changes in the spinal cord and ganglia are identical, and both may lead to varicella in contacts. Further, the occurrence of epidemics of zoster, the presence of inflammatory changes in the spinal cord and ganglia, the transmission of varicella from zoster and vice versa, and the presence of specific antibodies in the blood of zoster patients all support the view put forward 30 years ago by Head and Campbell,[5] that herpes zoster is a specific infection, with a predilection for the first sensory neurone. Injury to this neurone predisposes to the development of zoster ("symptomatic") which, however, may arise spontaneously ("idiopathic").

There are three possible explanations of the association of zoster and meningo-encephalitis. (1) It may be a coincidence. (2) A pre-existing meningo-encephalitis, by damaging the first sensory neurone, may lead to an outbreak of "symptomatic" zoster. (3) The virus of herpes zoster itself may by extension cause meningo-encephalitis. A review of the literature suggests that all three possibilities may be realised. Souques considered that in his case the occurrence of zoster eight months after the onset of encephalitis lethargica was a coincidence, though a "symptomatic" zoster cannot be excluded. The relationship between the encephalitis and the zoster is equally doubtful in Madsen's case in which the interval between them was five months. The remaining reported cases fall into two groups, (1) those in which the meningo-encephalitis preceded the zoster, and (2) those in which the reverse occurred. Netter's case 5 and Tilney and Howe's case fall into the former group, and should probably be regarded as "symptomatic" zoster. In the other cases, including our own, there was no evidence of any infection of the nervous system preceding the zoster. Certain clinical features emerge from a consideration of these cases. (1) Meningeal symptoms are prominent. (2) These often possess a local predominance corresponding to the situation of the zoster. Ramond points out that headache and cervical rigidity are associated with ophthalmic zoster, and Kernig's sign with a thoracico-lumbar distribution. Renon and Blamoutier's case further illustrates this point. (3) Myoclonus was present in Netter's cases 1 and 2, and in Gundersen's patient.

The evidence points to the occurrence of meningo-encephalitis and meningomyelitis due to the virus of herpes zoster. This view is supported by the following facts. There is reason to regard herpes zoster as an infective disease produced by a neurotropic virus. Although this virus primarily attacks the posterior horns and posterior root ganglia, extension of the inflammation to the meninges is indicated by the frequent occurrence of lymphocytosis in the spinal fluid in the absence of signs and symptoms of meningitis. In rare cases the latter may also be present, either localised to the region affected, or in a generalised form, their onset following several days after the first symptoms of the zoster.

Bedson and Bland's interesting observations are not conclusive proof that in our patient the meningo-encephalitis was due to the virus of zoster, for we have no evidence that this virus may not be present in the spinal fluid when "symptomatic" zoster complicates a meningo-encephalitis of other, but unknown, ætiology. Nevertheless, for the reasons given, we prefer the simpler and more natural view that the zoster virus was responsible for the whole chain of events.

We cannot here discuss the question of the relationship between zoster and varicella, raised once again by the cases of our patient and his son. But we may remark in passing that if varicella is closely related to the neurotropic virus of zoster it seems superfluous to look for some secondary invader to account for varicellar encephalitis and myelitis. These difficult matters well demonstrate the inadequacy of clinical pathological, and even bacteriological criteria for the distinction of what we described as "diseases," and indicate the need for a more dynamic and biological conception of an infective disease as the reaction of the individual to the causative organism.

SURGICAL TREATMENT OF ADHESIONS INTERFERING WITH ARTIFICIAL PNEUMOTHORAX.*

By Gustav Maurer, M.D.,
MEDICAL DIRECTOR OF THE SANATORIUM GUARDAVAL, DAVOS, SWITZERLAND.

(WITH ILLUSTRATIVE PLATE.)

Forlanini first recognised the prejudicial effect of pleuritic adhesions in artificial pneumothorax, and Gravesen and Matson independently noted that permanent cure was obtained in some 37 per cent. fewer cases with adhesions than in cases with complete collapse. Since the majority of adhesions are due to perifocal inflammation of superficial foci in the lungs, it is not astonishing that the pulmonary insertions of the adhesions are often directly over the walls of cavities. The bad effect of pleuritic adhesions being indisputable, from the very beginning of the pneumothorax treatment, many attempts have been made to deal with them, but with little success. The service Jacobaeus rendered to science when he devised his successful method in 1910 cannot, therefore, be too highly praised; indeed it is still very popular though it has many opponents. He uses a thoracoscope, similar in construction to a cystoscope. He anæsthetises an intercostal space and pushes a trocar with the cannula for the thoracoscope gently through the chest wall. By manœuvring the instrument in all possible directions, he examines the thoracic space and the shape, length, and thickness of adhesions —in short their operability. With the thoracoscope to guide, the galvanocautery is introduced in the same manner through a second cannula and is placed on the adhesion; the cautery is brought to a cherry-red glow, and the division is then made.

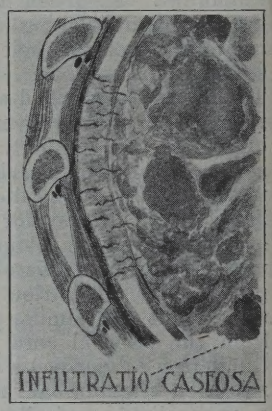
With this method a considerable improvement may be expected in 66 per cent. of cases. The most serious complication is empyema. According to the statistics of Jacobaeus and Unverricht, empyema must be reckoned with in 10 per cent., and tuberculous exudate in 15 per cent. of cases. It is well known that purulent exudate is a very serious if not a fatal complication. Although two-thirds of the cases can apparently be successfully dealt with, they have not the absolute guarantee but only the prospect of a permanent cure. The question, therefore, must be raised whether an extrapleural thoracoplasty would not be more favourable than an insufficient pneumothorax.

A Classification of Adhesions.

Empyema may arise from different causes; absolute sterility is rendered difficult by the thoracoscopy, and suppurative organisms may be brought into the pleural cavity by the operator himself; the eye-lashes of the face may touch the thoracoscopic eye-piece, and the operating hand may be contaminated while directing the instrument. However, realisation of these dangers should be a sufficient guarantee against exogenous empyema from such causes.

When we inquire into the origin of endogenous empyemata we must realise that the adhesions are not always truly fibrotic. Histological examination of 37 strands and membranes has convinced me that nearly three-quarters of the attackable adhesions contain lung tissue, and to this fact we must attribute the cause of the appalling percentage of empyemata. Since the majority of the adhesions are due to perifocal inflammation of superficial exudative or destructive foci in the lung, the parenchyma loses its vitality and is drawn out into a pedicle when pneumothorax is induced. Between the two extremes, on the one hand, a purely fibrotic adhesion, and on the other hand one which consists solely of parenchyma, there are all degrees of variation. Further histological investigation has shown that the pulling action of the adhesion and the weight of the lung can cause a tent-like projection of the parietal pleura. The majority of the larger adhesions, therefore, show the following threefold structure: firstly, parietal pleura with fascia endothoracica; secondly, the fibrotic bridge—that is to say, the symphysis between the two parietes; thirdly, the lung pedicle. (Fig. A.)

FIG. A.



Showing the threefold structure of the larger adhesion.

The shape of the individual adhesions gives such a definite indication of their structure that I have chosen it as the basis of a classification, which is of the utmost practical value, particularly in cases where, in consequence of a pleurisy, the pneumothoracic cavity is the same colour all over, so that neither parenchyma nor connective tissue can clearly be distinguished. As a basis indicating the advisability of operation we can, however, rely on the following classification:—

1. Adhesions of which neither the pulmonary nor the thoracic insertion is broadened out. They are the result of intrapleural symphysis occurring shortly before the induction of the pneumothorax. Their elasticity is very great and in consequence they stretch easily and almost without limit. Their division is not dangerous but its therapeutic effect is more or less illusory.

2. Adhesions of which the thoracic end is broadened out. In this class the symphysis is older, and has become fibrotic; its elasticity is therefore limited. The parietal pleura is projected in a tent-like manner. The therapeutic result of division is certainly better, but one very seldom comes across this type of adhesion.

3. Adhesions of which the pulmonary insertion is conical. In this case the pleuritic symphysis, owing to its long standing, is very dense. In consequence of exudative and destructive foci, the lung has little vitality, and is drawn out by the pulling action of the adhesion into a veritable pedicle. Rist and Brauer have published similar cases. This type is frequently met with and the majority of the empyemata are due to division of adhesions of this class. On the other hand, if no complications result, the best therapeutic effect can be attained with this class of adhesion.

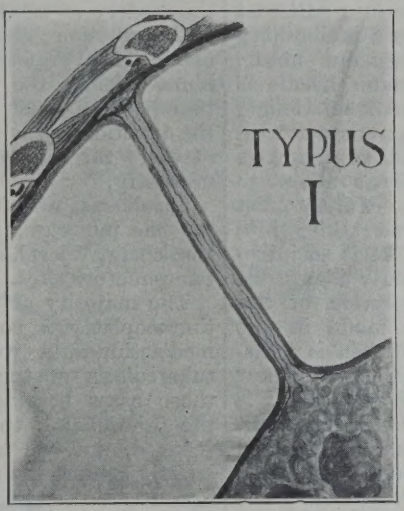
4. Adhesions of which both the thoracic and the pulmonary insertions are expanded, like an hour-glass. Between the tent-like projection of the parietal pleura and the pulmonary insertion the fibrotic bridge of the old pleuritic symphysis is to be found. The danger of endogenous infection is less than with type 3. The most important adhesions belong to this type.

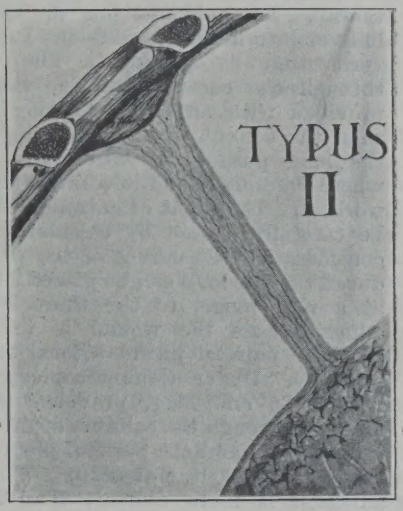
* A paper read before the Medical Society of London on Feb. 10th (see THE LANCET, Feb. 15th, p. 355).

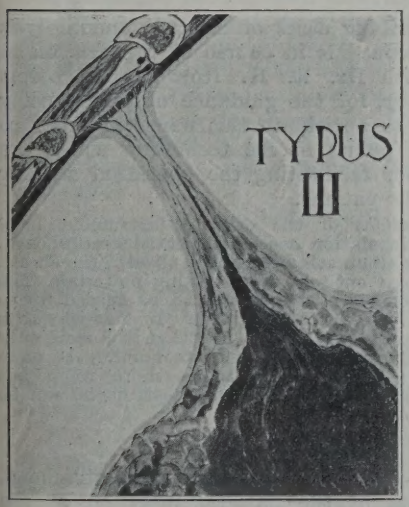
Necessity for "Enucleating" Adhesions.

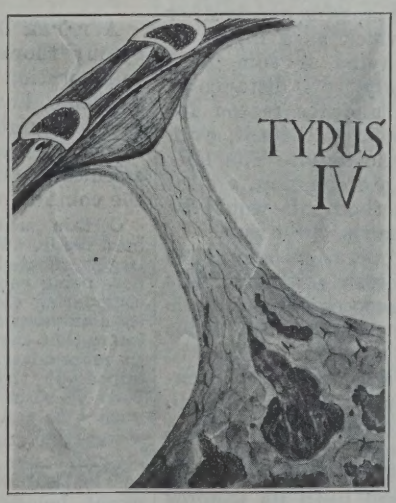
The thicker the adhesion the shorter and more serious it becomes, and the nearer the parenchyma approaches the chest wall. The operator therefore finds himself faced with the alternative of attacking only long drawn-out strings, which are only exceptionally a cause of the failure of the pneumothorax, or of running the risk of opening the bronchial system or even cavities in cutting thick and short adhesions. Jacobaeus, Unverricht, and others have pointed out the necessity of dividing adhesions as near as possible to their thoracic insertion. Their statistics support my assertion that this is not sufficient. "Division of adhesions," the technical term for the operation, is a term which itself implies an unskilful procedure. It is absolutely necessary to enucleate adhesions from the chest wall. With rare exceptions they consist in this situation solely of connective tissue and with this modus operandi only one lung stump results, together with a wound in the thoracic wall. Enucleation of the adhesion from the chest wall is possible neither with the instrument of Jacobaeus nor with its modifications. The insertions are generally well vascularised and there is a still greater danger, that of injuring an intercostal vessel. This complication is all the more dangerous, because in serious hæmorrhage, the thoracic cavity has to be widely opened for the ligature of the bleeding vessel. But even a small hæmorrhage has its importance in the ætiology of empyema. In consequence of this many attempts have been made to replace the galvanocautery by cutting diathermy, for instance by Hervé and by Maendel and Kornitzer, who have provided their instrument with a galvanocautery in order entirely to cauterise those adhesions which they are not able to divide with the cutting diathermy. This accessory instrument is not necessary, seeing that modern apparatus have been constructed which divide dense strands without difficulty. On the other hand, I cannot too forcibly point out the disadvantages of cutting diathermy. This method needs a current of such a strength that it is capable of causing deep coagulation. To illustrate this, take the case of a short adhesion. Even by working the cutting diathermy as near as possible to the chest wall one cannot prevent the lung pedicle as well as the line of division from becoming partly white. This portion of coagulated lung later on becomes necrotic and empyema results.

THE FOUR TYPES OF INDIVIDUAL ADHESION.









I worked out in 1927 and published in 1928 a method of my own.[1] I work with high-frequency currents of 0·1 to 0·3 ampère, just enough to produce a coagulation zone 2–3 mm. wide. I thus sacrifice all cutting effect in order to obtain a small and sharply defined coagulation area on the parietal pleura, close around the thoracic insertion. For the cauterisation the loop of the cautery is kept in the middle of this narrow coagulation zone. For very expanded insertions, diathermy and galvanic current have to be used alternately until the adhesion is completely enucleated. By this method all hæmorrhages can be avoided, the small current coagulating even intercostal vessels and, above all, no risk of wounding the lung is incurred. With my method I can considerably reduce the danger of subsequent empyema and enlarge the field of cases where operation is indicated. Of 130 cases operated upon, one developed empyema and another a tuberculous exudate. No patient died, either from direct or indirect causes. I cannot give you better proof of the efficacy of this method than these statistics. (See Plate, Figs. I. and II.)

[1] Brauers Beiträge, 1928, lxix., 246.

Author's Technique.

I introduce the thoracoscope at a point where the best view of the adhesion can be obtained. For apical adhesions the instrument is introduced in the nipple line, but it is seldom used behind in the interscapular region, where radiological exploration leaves us in the dark as to the dimensions of the pneumothorax. To avoid plunging the trocar into adherent lung or into invisible adhesions I make a preliminary verification by passing a fine Saugmann needle through the chest wall. The Saugmann needle is provided with an easily slipping wire 2 cm. longer than the cannula itself. The slightest contact with the lung pushes the wire back, and so indicates where the lung is and how much space is available to work in. The point of entrance of the cautery must be carefully chosen by calculating and taking into consideration the curves of the ribs. It is so introduced that its loop can be placed as nearly as possible at a right angle to the thoracic insertion of the adhesion. As the wound is to be made in the sensitive parietal pleura a local anæsthesia is indispensable. Under thoracoscopic guidance a hollow needle, 25 cm. long, provided with a syringe, is directed through the cannula of the cautery, and both the adhesion and the parietal pleura are anæsthetised with 0·4 per cent. novocain. The enucleation of an adhesion is more difficult than its division. The instrument used for this work of precision must therefore be light and at the same time stable, and must slide easily in the cannula. To facilitate the alternative use of the two currents I have constructed a combined cautery, the galvanocautery loop acting also as the therapeutic diathermy electrode. The electricity supply is regulated by a foot control with pedal switches on opposite sides, so that the hand directing the cautery does not lose its balance. By means of this apparatus I am able to deal with big and short membranes as thick as a finger, situated one behind the other, or adhesions crossing one another or with rope-like adhesions as thick as a humerus. In such adhesions the parenchyma is sometimes separated from the chest wall only by a distance of some millimetres, which is yet another reason for working practically on the thoracic wall itself, even at the risk of damaging the periosteum. The long thin adhesions of type 1, which are common, are, of course, divided by the usual method; it would be superfluous to enucleate them from the chest wall.

The field of indication for the operation being thus extended I continually come across veritable walls of short adhesions. With the thoracoscope we only see in one direction and consequently only get one surface into the visual field. We have, therefore, always to bear in mind that behind the adhesions the parenchyma may be directly in contact with the chest wall.

In order to avoid burning into the lung or into a cavity I have constructed a sound of the diameter of the cautery, which slides easily into the cannula. The instrument is pushed forward until its window touches the free border of the membrane, the cross-beam with which it is furnished is placed on the invisible wall of the adhesion and, by carefully retracting the instrument, an approximate idea of the thickness of the invisible part can be obtained.

I was interested to read in THE LANCET of Feb. 1st an article by Dr. F. G. Chandler, who has adopted the principles of my method, which I am convinced is the best method of burning adhesions. He differs from me inasmuch as his instrument contains thoracoscope, coagulating electrode, and cautery in one, resembling in construction those of Maendel and Kornitzer but having several advantages. Personally, I find it preferable to work with two punctures. The introduction of the trocars is, after all, the simplest and easiest part of the operation. The enucleation of the adhesion can be done more precisely with a straight and stable cautery, which slides easily into its cannula and which is quite independent of the thoracoscope in its movements. It is necessary to place the loop of the cautery at right angles to the thoracic insertion of the adhesion; this cannot be done with the guidance of the X ray pictures only, even with stereoscopic films. Before the introduction of the cautery the thoracoscope must be introduced in order to study the direction of the adhesion and to find the best point of entry for the cautery, and so two punctures are necessary.

Jacobaeus, who in 1924 made various attempts to use one puncture, shares my opinion, and Frisch, Eiselsberg, Wiegel, and Kremer have all gone back to two-puncture sites.

The majority of difficult divisions are cases where thoracoplasty is counterindicated owing to a weak mediastinum, a weakness of the myocardium, or tuberculosis of the other lung. The operation in those cases becomes decisive and life saving. On the other hand, the complications are considerably reduced, and we have, therefore, no reason to be strictly against the performance of the operation.

THORACOSCOPY AND INTERNAL PNEUMOLYSIS.

POINTS IN TECHNIQUE.

BY F. G. CHANDLER, M.D. CAMB., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL; PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK.

A PAPER describing cases of internal pneumolysis by my thoracoscope[1] is in course of preparation in collaboration with Dr. R. H. Howells. It seems desirable, however, for the guidance of others using this instrument to anticipate this paper in order to describe certain points in the technique which are essential, both for facilitating the operation and for the comfort of the patient.

Certain *modifications* of the original instrument have been made. The insulation has been greatly strengthened, largely effected by eliminating the metal sheath, the sheath now being composed entirely of insulating material. The coagulating electrode is now intended to be turned up to its maximum and used in this position. In this way it is found that the illumination is best, and that it is more easy to manipulate. Further, realising that mobility is more important than absolute air-tightness, more room has been given in the cannula so that the instrument can be pushed to and fro easily.

Localisation.

The thoracoscope, being a one-puncture instrument, exact localisation of the parietal insertion of the adhesion is essential, for often it is at the parietal end, if not actually on the chest wall, that the adhesion must be divided. The decision in what interspace to insert the cannula, and whether to go into the front of the chest or the back, or the axilla, must depend entirely on this localisation. If a mistake is made or if a wrong point of entry is chosen the instrument may not touch the parietal end of the adhesion, or will do so only with difficulty and much pressure of the cannula on the patient's chest; or it will be

[1] THE LANCET, 1930, i., 232.

found that there is not sufficient room in which to work and there is danger of withdrawing the thoracoscope too much so that "shorting" takes place between the instrument and the cannula. This localisation is achieved by a study of the skiagram and by screening the patient. The horizontal plane of the insertion can usually be determined without difficulty. What cannot be learned from the skiagram is whether the adhesion is inserted anteriorly or posteriorly to the midaxillary line. This can be determined by rotating the patient during screening. If the adhesion appears shorter whichever way the patient is rotated, the adhesion must be inserted in the midaxillary line.

If an adhesion in the right pleural cavity is inserted anteriorly to the midaxillary line (Fig. 1, A), and the patient

FIG. 1.

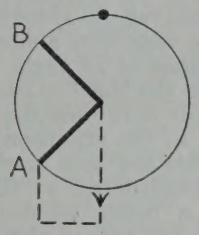


FIG. 2.

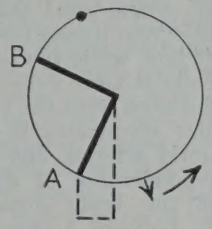

is rotated to the right oblique position (Fig. 2), the adhesion will appear to become shorter; if it is inserted posteriorly to the midaxillary line a similar rotation will make it appear to become longer. If the patient is rotated to the left oblique position, the reverse will occur. Contrariwise, if an adhesion in the left pleural cavity is inserted anteriorly to the midaxillary line and the patient is rotated to the right oblique position, it will appear to become longer, if posterior to the midaxillary line it will appear to become shorter as a diagram similar to the above, made on paper, will readily show. If the patient is rotated to the left oblique position the reverse again will occur. We are, therefore, able to say whether an adhesion is inserted anteriorly or posteriorly to the midaxillary line. If the adhesion cannot be seen on screening skiagrams can be taken in these positions.

Localisation having been determined, a position is selected on an actual skeleton which would be the optimum point of approach for the instrument, remembering that it is not safe to go nearer than one inch to the sternal border or nearer than one inch to the border of the spine. At Victoria Park Chest Hospital, thanks to Dr. J. V. Spark's most valuable coöperation, we have found this method most successful.

Anæsthesia.

Local anæsthesia, from within, of the part to be operated on is essential. General anæsthesia, though abolishing the consciousness of pain, does not abolish the severe muscular spasm which may result from local heating effects of the diathermy current concentrated on a small area. With proper local anæsthesia, pain and the spasm phenomenon are both completely eliminated.

After a preliminary survey, the needle telescope is inserted or the preliminary survey may be made by the needle telescope itself.

This has been considerably modified since the first description of the instrument. It consists of a direct vision telescope with a very wide field of vision, and a lamp on a flexible shaft, giving brilliant illumination. The instrument is assembled with the lamp on its flexible shaft, projecting beyond the end of the telescope a distance equal to the length of the cannula. This is inserted through the cannula, then the telescope is pushed in afterwards. By this device, an instrument double the width of the cannula can be inserted into the chest through the cannula.

If a favourable position has been chosen, the telescope will point directly at the insertion of the adhesion. The needle should be pushed out as far as possible in order to get a good bird's-eye view of the part to be anæsthetised. A moment's consideration to get the proper orientation will tell the operator which way the nerves are running to the adhesion. The needle is inserted just under the parietal pleura at the spinal side or surface of the adhesion, and 2 per cent. novocain is injected. If the adhesion is between the instrument and the spine the adhesion can be pierced by the needle and the pleura beyond it injected. It is then advisable to inject several places along the width of the insertion, and even to put some local anæsthetic into the adhesion itself. It can easily be seen forming a bleb. If anæsthesia is complete, the patient will feel nothing, and there is no muscle twitching.

The Diathermy Machine.

The new technique of severing adhesions comprises two distinct operations: (1) the coagulation of a suitable portion of the structure, and (2) the actual cutting through the coagulated portion. For this a machine of special design is required. The ordinary diathermy apparatus used for treatment is useless because it will not cut. It has been demonstrated that a high-frequency current composed of sustained oscillations will cleave the tissues in the same way as a knife, but apparatus for production of continuous sustained oscillations is very complicated and costly. It requires a direct current of very high voltage and a thermionic valve. In practice a current composed of slightly damped groups of oscillations has the desired effect.

This current may be obtained by applying an alternating current to a circuit composed of a condenser, inductance and a thermionic valve. The last can, with advantage, be replaced by a specially designed spark gap. It is essential for clean cutting to use a very high oscillation frequency. Further, the damping losses must be reduced to an absolute minimum, otherwise only a very small current will flow in the circuit. The oscillation frequency is determined by the capacity of the condenser, and the inductance (size and number of turns of the coil) and must be of the order of 5 to 6 million cycles per second.

Such a machine has been designed by Mr. Schranz, of the Genito-Urinary Company, and it is to him that I am indebted for the technical description of the instrument.

It is fitted with a selector switch graduated from 0 to 10. Experience has shown that coagulation of an adhesion can be effected with the machine at zero. This will give deep coagulation. If the white zone of coagulation can be seen extending too far, or if coagulation is taking place too slowly, or if the adhesion is very short, and intensity rather than distance or depth of coagulation is wanted, the machine must be turned to 1 or 2. For cutting, the machine may be used from 2 onwards. Usually 2 or 3 is sufficient. This depends on the resistance of the adhesion, which unfortunately may vary in different parts of the same adhesion. It is better to be on the safe side and start too low; the machine can be turned on notch by notch until the required intensity is reached.

Over-coagulation produces great resistance. Sometimes if a cord adhesion has been over-coagulated, attempts at cutting it only succeed in completely carbonising it, and with the machine all out at 10 it may not yield. In such a state the adhesion can be broken by a blow from the electrode. If this is not possible I have devised a thin knife-edge that can be inserted through the needle telescope. This, in fact, could be used immediately after coagulation. Of course, such over-coagulation theoretically should not occur, but for beginners, at any rate, it is better to err on this side than to have arterial spurting if only from a minute arteriole.

It is essential to have good contact between the patient's body and the indifferent electrode. Careful observation should be made to see that the patient's body is lying firmly on the electrode. The electrode must be of ample cross-section, and its covering pad be kept thoroughly moist with salt solution.

CLINICAL AND LABORATORY NOTES

A CASE OF CARCINOMA OF THE BREAST

SUGGESTING THAT RADIUM CAN STIMULATE THE GROWTH OF CANCER CELLS.

By W. H. C. Romanis, M.Chir.Camb., F.R.C.S. Eng.,

ASSISTANT SURGEON TO ST. THOMAS'S HOSPITAL; SURGEON TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

It has long been held by many surgeons that under certain circumstances X rays or radium might be capable of stimulating the growth of cancer cells instead of destroying or inhibiting them. It has even been thought that insufficient or improperly applied dosage might be responsible for this. At the same time it is a difficult matter to prove, and I have on one or two occasions heard enthusiastic radio-surgeons state that they did not believe it, and had never seen a case of the kind. The following case is undoubtedly very suggestive that an actual stimulation by radium of carcinoma cells has occurred.

Miss A. B., aged 55, was sent to me by Dr. Harry Smith, who had only seen her for a few days, with an advanced carcinoma of the breast. As the skin was slightly infiltrated, the growth adherent to the muscles underneath, and large hard glands present both in the axilla and the supraclavicular fossa, it was decided that the growth, was inoperable in the ordinary sense of the term, and it was determined to use radium needles of 1·0 mg. each by the usual technique of implantation for 14 days. Thirty needles were implanted at the usual sites — i.e., in a circle round the periphery of the growth, in the axilla, in the supraclavicular fossa, the intercostal spaces, &c. The main bulk of the growth diminished considerably in size though it never completely disappeared, while the supraclavicular and axillary glands at any rate remained stationary, and possibly also diminished slightly. Within six months, however, hard nodules, varying in size from a dried pea to a hat-pin's head, had appeared in the skin in every one of the needle punctures surrounding the growth. These were typical secondary nodules, hard, prominent, red, and adherent to and infiltrating the skin. These continued slowly to increase in size until the patient died shortly afterwards.

As the recurrent nodules occurred exactly in the line of and at the spot of introduction of the radium needles, it is difficult to resist the conclusion that at these particular spots, at any rate, there was some stimulation or encouragement of the growth of carcinoma cells.

THE PREVENTION OF THROMBOSIS.

By C. A. J. Quant, M.D.,

DIEPENHEIM, HOLLAND.

It is well known that thrombosis occurs more often in the left leg than in the right, both after operation and after delivery, in the form of phlegmasia alba dolens. Even after appendicectomy the thrombosis is usually seen on the left side. This curious fact does not receive the appreciation it deserves, despite the large amount of work that has been done on the causes of pelvic thrombosis. It suggests that the thrombosis is not in direct connexion with the veins of the wound of the operation, or with the inside of the uterus, and that some anatomical explanation is likely to throw light on the causation of thrombosis.

All authorities agree that slowing of the blood stream is one of the most important of the possible causes of coagulation, especially if there is a constriction in the vessel. The veins of the pelvis are asymmetrical and bear a different relation to the corresponding arteries. The inferior vena cava is formed on the right-hand side behind the origin of the iliac arteries, while behind Poupart's ligament the arteries lie lateral to the veins. The arterial system is more symmetrical than the venous system; the right iliac vein passes into the vena cava almost in a straight line, while the left enters at an angle. This must make it more difficult for the blood to pass into the vena cava from the left side than from the right. A similar asymmetry is seen in the arrangement of the carotid arteries, and to this has been attributed the preponderance of right-handedness, as the left side of the brain obtains a better blood-supply. Prof. L. Bolk, of Amsterdam, has proved that more blood passes through the left carotid than through the right. Another example of asymmetry is seen in the spermatic veins; the left vein enters the left renal vein almost at a right angle, and varicocele nearly always appears on the left side.

This obstruction to the return of blood from the left leg and left side of the pelvis makes itself fully felt owing to the absence at this place of fatty packing between the veins, the arteries, and the bones. The German surgeon Riedel noticed that the right iliac artery crosses the left iliac vein transversely and at the same point the middle sacral artery crosses behind the vein. These two arteries, therefore, hold the vein between them like a pair of forceps and must cause constriction just before the dilatation due to the union of the vein with the right iliac. Another more caudal constriction occurs on the left side where the hypogastric artery crosses the iliac vein. That pressure of this kind may have pathological results is shown by the weakness of the right arm and right pulse when the subclavian artery comes off the descending aorta and passes between the vertebral column and the œsophagus.

THE EFFECT OF LYING ON THE BACK.

Thrombosis chiefly occurs in patients who have been on their backs for a week or more at a time, when the action of the heart and the effects of muscular contraction on the vessels are reduced; there are, therefore, very likely to be dilatations on the cranial side of the strictures with whirlpool formation and sedimentation of thromboblasts. The whole pelvis will be an "area of least resistance," and the minimum pressure will be found on the left side. The possibility of compensating for the hæmostasis by collateral circulation is less on the left side, since the hemi-azygous system is smaller than the azygous system and has to cross at a right angle between the aorta and the dorsal vertebræ.

It seems possible that the "strangulation" of the left iliac vein by the right iliac and middle sacral arteries is increased when the legs are stretched out in dorsal decubitus, and this may be one reason why few people sleep in this position for long at a time. The extension of muscles, tendons, and ligaments also

helps to make the circulation of the blood more difficult.

We know nothing as yet of the cause of thrombosis, but there are certain conditions in which it occurs relatively often. These are anæmia, adiposity, enteroptosis, old age, and the results of Spanish influenza. In all these the action of the heart is weakened, and the patients who suffer from thrombosis seem all to have been quiet and to have tried to move as little as possible after their operation or delivery. There must, however, be some determining cause in the actual operation, for thrombosis does not occur even in the strictest rest cures—e.g., after hæmatemesis. Roegholt, a Dutch specialist in the East Indies, has pointed out that he never saw a case of thrombosis there, either in Europeans, natives, or Chinese, and he was struck by its relative frequency when he returned to Holland. He attributed the difference to the great heat and the mosquitoes, which, together, make the patients in the tropics much more restless. The greater restlessness of young people may perhaps account for the absence of thrombosis under the age of 20. Restlessness has another consequence, for it loosens the bandages. Tight bandaging, especially round the abdomen, may possibly increase the difficulty in the blood flow, and it helps to limit the action of the abdominal muscles.

SUMMARY.

Subject to the fulfilment of other conditions, slowing of the blood stream is probably the determining cause of thrombosis. Statistics show that this nearly always occurs on the left side of the pelvis, which is, perhaps, the weakest link in a chain. Anatomical considerations show that strictures and whirlpool formation are very likely to occur in the iliac vein in this region, and the possibility is greatly increased by long confinement to bed, lying with outstretched legs, tightly tucked-in blankets, and a tight bandage round the abdomen and hips.

The obvious lesson is that patients should be moved as soon as possible and allowed to get up for short periods several times a day.

"MASTOID DYSPEPSIA" IN A CHILD.

BY LINDSEY W. BATTEN, M.B. CAMB., M.R.C.P. LOND.,

VISITING MEDICAL OFFICER, CHILDREN'S HOSPITAL, HAMPSTEAD; ASSISTANT PHYSICIAN, EAST LONDON HOSPITAL, SHADWELL.

THAT dyspepsia in infancy, whether acute or chronic, is often the main symptomatic expression of an infection outside the intestinal tract is, of course, well known, and of late years special attention has been paid, especially in the United States, to otitis and mastoiditis as causes of diarrhœa and vomiting.

AMERICAN VIEWS.

L. E. Hetrick,[1] in a recent review of the subject, quotes Renaud as finding pus in the mastoid antra of 70 infants dying of gastro-intestinal disturbances in 1921, and states himself that of 30 cases of mastoiditis at the St. Louis Children's Hospital 56 per cent. had the symptom-complex of increasing temperature, diarrhœa, vomiting, loss of weight, and athrepsia. L. W. Dean,[2] writing on the same subject, states that dehydration, refusal of food, diarrhœa, and loss of weight may be the factors that will decide whether myringotomy should be performed. "They may indicate mastoidectomy," he says. "If otitis be present it can always be diagnosed." M. L. Floyd[3] describes the same clinical picture, adding that the bowel condition does not respond to diet rearrangement and that the mastoiditis is masked. He holds that "bilateral mastoidectomy performed as soon as the condition is determined and other foci eliminated has resulted in prompt recovery of many of these infants and is probably the only means of saving the child's life."

On the other hand, L. Richards,[4] of Chicago, analysing a considerable group of cases is inclined to question the causal relationship of the dyspepsia to the otitis or mastoiditis, is not impressed by the effect of surgical treatment of the ear condition on the course of the disease and finds that mastoidectomy has no advantage over myringotomy in this respect. "Operation, regardless of whether an infected mastoid antrum had been drained or not, did not appear to have improved the patient's general condition to any appreciable extent. The feeling was always borne in on us that the babies were too sick to benefit by having a subsidiary condition remedied."

Little seems to have been written on the question in this country.

A CASE NARRATED.

A boy, aged 11 months, was admitted to the Children's Hospital, Hampstead, on Feb. 19th, 1930, primarily because a small superficial sore on the glans penis following circumcision at the hospital was causing concern to his parents. The following history was elicited later.

Six days before admission he had been quite well. He was taken to a welfare centre on that day and weighed 21 lb. On the next day he had some pain in the left ear and a discharge from it on the night following. He had no diarrhœa or vomiting.

On admission he had a temperature of 100·4° which fell to 98° on the next day. I saw him first on March 2nd. He then weighed 19 lb. 8 oz. and had the appearance of a child with a toxic dyspepsia such as might arise from wrong feeding or gross underfeeding in a bad environment. (Actually his home conditions were good and his parents careful and not ill-informed.) He was pale and listless, taking little notice of his surroundings and not attempting to sit up. His skin was dry, his muscles very flabby. There was a muco-purulent discharge from the left ear, the tonsils were very slightly enlarged, and a few glands were palpable in the neck. Nothing abnormal was found in the chest or abdomen. No teeth had erupted but he was otherwise well-grown and there was no clinical evidence of rickets in the bones. Since March 29th his temperature had been normal; he was constipated and his appetite was poor.

A mixed diet, suitable to his age, was ordered and "open-air treatment" on the balcony, weather permitting. I saw him again on April 6th. On this day he had begun to vomit his food, he looked less well, but there were no new physical signs. He now developed a severe dyspepsia. His stools became frequent, loose and then watery, though yellow in colour. He refused food and vomited what he was induced to take. Citrated milk and water mixtures, Benger's food and whey, whey alone, glucose and water, and even water were vomited, prostration and listlessness became extreme, and he lost weight rapidly, reaching 18 lb. 7 oz. on April 9th.

The manner of onset of the dyspepsia and its complete lack of response to dietetic and other treatment suggested that it might be symptomatic and due to some parenteral infection. There was no evidence of any such infection except in the ear and, with the American literature in my mind, I asked Mr. C. Gill-Carey to see him. He found the right ear normal, the left apparently draining freely, and no signs of mastoiditis on either side, but we agreed that in view of the child's general condition the left mastoid ought to be explored. Normal saline subcutaneously and glucose solution by the rectum were given to combat dehydration, and on the evening of April 10th the left mastoid was explored by Mr. Gill-Carey under local anæsthesia. Small beads of pus were found scattered throughout the softened bone. Mastoidectomy was performed, the cavity was packed with gauze smeared in bismuth iodoform paste, and the wound left widely open. A swab taken from the pus grew hæmolytic streptococci.

The child was very little disturbed by the operation and there was no shock. Next day he took and retained his feeds well, the bowels acted less frequently, the stools improved, and he was much more alert. Improvement continued for four days but on the fifth he relapsed. Vomiting, prostration, and refusal of food returned, there was slight fever and a rapid pulse, and he again looked very ill. The right ear-drum, which had been normal, seemed to me to be no longer so, and I asked Mr. Gill-Carey to examine it again. He found signs suggesting fluid in the middle ear though there was no redness or actual bulging of the membrane and no mastoid tenderness, and it was decided to perform right mastoidectomy. This was done, again under novocain anæsthesia, and pus was found in the bone.

The child bore the second operation less well than the first. There was some febrile reaction, and though vomiting ceased the stools continued to be loose and frequent for another five days. After this, however, a very definite improvement began and was maintained, the weight rising from 17 lb. 10 oz. on April 28th to 20 lb. a month later. Two slight setbacks appeared to be due to partial blockage of drainage, on the first occasion from the nearly healed right mastoid sinus and on the second from the left ear, the chief symptom in each case being loss of appetite. The boy is now very well and on June 17th weighed 22 lb. 2 oz. Both mastoid sinuses are healed and the discharge from the left ear is very slight.

In view of the experiences of Richards quoted above it may be that we were fortunate in the outcome of the case, but the apparent effect, especially of the first operation, in reversing the course of a rapidly progressive toxic dyspepsia was immediate and pronounced; relapse appeared to synchronise with the onset of trouble in the second ear, and it is hard to believe that the dyspepsia was not secondary to the mastoiditis or that myringotomy or anything short of what was done could have had a like effect.

A CASE OF CONGENITAL SYPHILIS WITH SYPHILITIC MENINGITIS.

BY R. STRÖM-OLSEN, B.SC. WALES, M.R.C.S. ENG., D.P.M.,

SENIOR ASSISTANT MEDICAL OFFICER, BOROUGH MENTAL HOSPITAL, ROWDITCH, DERBY.

IN THE LANCET of June 21st Dr. Kramer described a case of syphilitic meningitis in an adult with acquired syphilis. The following case forms a contrast. A boy of 15 was admitted to the Mental Hospital at Rowditch suffering from restlessness and a high degree of mental confusion. From the previous history was elicited that up to the age of 7 he was subject to an occasional convulsive attack, and at that age also contracted scarlet fever. From the age of 7 to 14 he appeared normal and attended school regularly. In the beginning of November, 1929, he began to suffer from headache, listlessness, impairment of memory, and abnormal sleepiness. Gradually the mental condition deteriorated; motor restlessness and insomnia supervened.

On admission, Nov. 23rd, 1929, he was very confused, irritable, and restless, and continually making whining noises. He gave no indication of understanding what was said to him, and could only utter a few simple words. He was easily angered, and then fell into a state of uncontrolled frenzy.

Physical Examination.—Poor physique, fairly nourished; ears large and flattened, palate high-arched and narrow, frontal bossing. The central incisors were peg-shaped and notched. Temperature normal, pulse 90 per minute. Pupils dilated and reacted very sluggishly to light, cranial nerves normal. Knee-jerks brisk, plantar reflexes gave a flexor response. Albuminuria present.

Serological examination gave the following results: Kahn reaction of blood and C.S.F. strongly positive (++++). The cerebro-spinal fluid escaped under slightly increased pressure, was clear, and gave no coagulum on standing. Seventy cells per c.mm., chiefly lymphocytes, but some plasma cells were present. The colloidal gold curve was of the paretic type (5533322100), and globulin was considerably in excess.

A diagnosis of juvenile general paralysis was made. Owing to his exhausted condition and the albuminuria, however, neither malarial nor salvarsan treatment was undertaken. On Dec. 4th he began to develop syphilitic ulceration around the anus, which was successfully treated by mercurial inunction. A fortnight later his physical condition became distinctly worse with marked wasting and difficulty in taking food. The temperature was slightly raised on three or four occasions, otherwise remained normal throughout. A week before death meningeal symptoms became very prominent with pronounced head retraction, positive Kernig's sign, widely dilated and inactive pupils, Babinski's sign, and gradually increasing blindness. His whining noise had now become a typical meningitic scream. On Dec. 30th he merged into coma, and died two days later.

At *autopsy* the brain showed an extensive meningeal exudate of a milky colour, especially well marked over the convexity and in the Sylvian fissure. It was quite unlike the milkiness of the membranes seen in the paretic brain and much more profuse. No tubercles or gummata were visible. The exudate over the lateral aspect in places approached 2 mm. in thickness. The lower parts of the frontal and parietal lobes showed considerable flattening and shrinkage of the convolutions. There was but little meningeal exudate at the base of the brain. Some degree of internal hydrocephalus was present with excess of cerebro-spinal fluid. Granulations could be seen on the floor of the fourth ventricle. Microscopical examination showed the exudate to consist of lymphocytes (chiefly) and plasma cells. The pyramidal cells showed varying stages of chromatolysis and capillary proliferation with perivascular cuffing, indistinguishable from that seen in general paralysis.

The feature of this case is the development of syphilitic meningitis manifested by the pronounced meningitic symptoms, and further confirmed by the extensive inflammatory exudate on the surface of the brain, whilst at the same time there were physical signs, serological evidence—e.g., paretic gold curve—and certain anatomical signs of juvenile general paralysis.

My thanks are due to Dr. John Bain, medical superintendent, for permission to publish these notes.

SCARCITY OF NURSES IN SCOTLAND.—Speaking at the annual meeting of the Edinburgh Club for Nurses recently, Dr. Parlane Kinloch, chief medical officer of the department of health for Scotland, expressed the fear that at an early date there will be an acute scarcity of trained nurses. An enormous number of women, he said, after they were trained as nurses, went abroad owing to the fact that in the colonies and the United States the prospects were better. Rectification must be looked for in better organisation of training, better status, and better emoluments. He suggested that all the representatives of the nursing profession should come together and endeavour to devise a policy under which nurses should be comprehensively trained. A medical student had five years of intensive training, and was led through the whole gamut of medical experience, but if a nurse wished to get to the head of her profession she must take three years' training in a general hospital, three years in a fever hospital, six months for maternity training, a year to a year and a half for mental disorders, and so on. This was an impossible state of affairs. He thought it might be possible to recruit girls at 16 or 17, and have four principal nursing colleges—at Edinburgh, Glasgow, Aberdeen, and Dundee—to which they might be sent for preliminary training.

MEDICAL SOCIETIES

PATHOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND.

A MEETING of this Society was held at Manchester on June 27th–28th with Prof. J. S. DUNN in the chair. The membership is now 533.

J. CRUICKSHANK (Aberdeen) had been searching for *B. lactis aerogenes* in normal fæces, and had found it in 98 of 135 cases; like many bacteria it was more common if it was specially looked for. He also detailed some curious observations on the capacity of different microbes to ascend a strip of blotting-paper along with ascending water. *Coli*-like bacteria climb best, irrespective of their motility. Tetanus does not go up, nor do pasteurellas; hæmolytic streptococci hardly rise at all, while the pneumococcus climbs well. The differences may perhaps be due to differences in electrical charge. The method may be used practically for separating mixtures of bacteria.—A. T. GLENNY and MONA LLEWELLYN-JONES (London) had carefully compared the various in vivo and in vitro methods of titrating diphtheria antitoxin, and found that the ratio between the animal test and the flocculation test was always the same with sera of any practical value; anomalous results were sometimes obtained with old or weak sera.—E. M. DUNLOP (Glasgow) found that there was a constant difference between normal and syphilitic sera in a simple lipoid flocculating system.—G. L. TAYLOR (Cambridge) pointed out that by using Dean's method of optimal proportions a mixture of two precipitins could be correctly titrated, and the amount of residual antibody in an antigen-antibody test could be determined.—J. GORDON (Leeds) described the effect of Congo red in preventing hæmolysis by a serum hæmolysin owing to its combination with complement. The dye does not react with the blood corpuscles.—J. M. ALSTON, G. R. GALBRAITH, and D. STEWART (Edinburgh) found that the soluble specific substance of type I. pneumococci strongly inhibited the bactericidal action of whole blood on the pneumococci, and also gave very definite reactions in intradermal inoculation into patients convalescent from pneumonia due to type I. but not in those who had been infected with the other types.—R. W. FAIRBROTHER and W. T. J. MORGAN (London), after prolonged immunisation of a horse, had obtained a serum which had a clear action in protecting monkeys against the virus of poliomyelitis, the horse being dosed with emulsions of the central nervous system of infected animals. A second horse gave entirely negative results.—C. H. BROWNING, D. F. CAPPELL, R. GULBRANSEN (Glasgow) had failed to get evidence that splenectomy made mice more susceptible to *Trypanosoma congolense*.—C. H. BROWNING and R. GULBRANSEN (Glasgow) described how the infection of mice with *Spirillum muris*, after a preliminary septicæmia, settles down to a stage in which the organisms can be demonstrated by inoculation but not microscopically. So long as this lasts, a fresh dose does not lead to any septicæmia, but if the animals are really cured by, e.g., salvarsan, septicæmia follows.—J. F. GASKELL (Cambridge) showed that subcutaneous doses of 1·0 g. of alcohol per kg. body-weight given daily for about three weeks much depressed the resistance of rabbits to the pneumococcus, though the animals gained weight and seemed in excellent health. Incidentally he had noticed that pregnancy definitely increased resistance. He also described some cases of fatal puerperal septicæmia in which infection seemed to be kept up by an infected clot in the iliac veins after the uterus has involuted in a normal manner.—C. E. JENKINS (Salford) showed and described his flicker hæmoglobinometer, which he claimed was more accurate than the usual methods.—G. R. CAMERON (London), working with artificial precipitates, bone, and calcified arteries, showed that neither the von Kossa test with silver nitrate nor hæmatoxylin were really tests for calcium. The former is given by a variety of phosphates, carbonates, and oleates; the latter stains something which often accompanies calcium deposition, but not calcium salts. Alizarin is the only specific stain, and this is not always easy to bring off.—C. POLSON (Leeds) had produced extensive liver necrosis by intraperitoneal administration of a carcinogenic shale oil; it might lead to a hobnailed liver. Similar oils which were not carcinogenic did not have this effect.—I. BERENBLUM (Leeds) showed that blast furnace tar might be carcinogenic, though it was generally said to be harmless.—L. F. FOULDS (London) described a slow-growing transplantable mouse sarcoma composed of mast cells.—R. WHITEHEAD and G. JEFFERSON (Manchester) described a papilliferous cystoma of the petrous bone, the origin of which could not be determined.—R. CRUICKSHANK (Glasgow) presented a study of the occurrence and properties of Döderlein's vaginal bacillus, which was easy to grow and anaerobic, and associated with the presence of an acid secretion.—K. V. BAILEY (Manchester) summarised his studies of the origin of carcinoma of the cervix, and emphasised the importance of the action of an inflammatory exudate on the basal layers of the epidermis. J. BRAXTON HICKS (London) showed a case of porencephaly, and said that there was no acceptable explanation of the anomaly.

DEMONSTRATIONS.

Among the demonstrations were: J. S. DUNN (Manchester), an enormous œsophageal varix; diffuse metastatic melanosis of the meninges; acute hæmorrhagic pancreatitis with impacted gall-stone. H. GARNETT WRIGHT and J. S. DUNN (Manchester), fibrous carcinoma of pylorus. W. SUSMAN (Manchester), paragangliomata of the suprarenal, human and bovine. J. H. BIGGART and A. M. DRENNAN (Belfast), persistent eosinophilia with localised infiltrations. JANET S. F. NIVEN (Cambridge), the repair of embryonic bones in vitro after fracture. M. J. STEWART (Leeds), asbestosis bodies in the lungs of guinea-pigs living in an asbestos factory. E. R. FLINT, H. WOLFE, and M. J. STEWART (Leeds), permeation of the Haversian canals of the skull by an arachnoidal endothelioma with hyperostosis. F. F. HELLIER and M. J. STEWART (Leeds), atrophied adrenals in Addison's disease. C. POLSON (Leeds), congenital malformations of œsophagus and trachea and of the ileum. J. MILLS (Reading), plasma-celled myeloma. W. H. TYTLER and J. B. DUGUID (Cardiff), a reticulum cell endothelioma of mediastinal glands (? carcinoma of lung). G. HASWELL WILSON (Birmingham), organs from a case of psittacosis. A. L. TAYLOR (Bristol), diffuse sarcomatosis of stomach and intestines with secondary cutaneous deposits.

EDINBURGH OBSTETRICAL SOCIETY.

AT a meeting on June 11th, with Dr. H. S. DAVIDSON, the President, in the chair, a paper on

Habitual Abortion

was read by Miss E. V. CROWE. This condition, she said, was by no means always associated with spirochætal infection, and during the past two years 19 non-syphilitic cases had been treated at the

antenatal department of the Royal Maternity Hospital, Edinburgh. In nine of the cases the abortions were preceded by a full-time, often instrumental, labour. Two of the 19 patients were suffering from toxæmia, five from cervicitis, one from pyelitis, and two from valvular disease of the heart. All showed general debility made manifest by anæmia, emaciation, sallowness, listlessness, headaches, constipation, and loss of appetite and strength. All had enjoyed fairly good health until their first pregnancy, after which this chronic ill-health developed. The majority lived in the poorer districts of Edinburgh, where both fresh air and sunlight might have been lacking. The average number of pregnancies was five in the short space of five and a half years—and this might be of some significance. Dental caries or pyorrhœa was present in 11, and septic tonsils in five. All were treated in much the same way, with repeated doses of neokharsivan and a special diet which was rich in calcium. They also had special treatment for the cervix, teeth, &c., where necessary. The results were, in the main, satisfactory.

Abdominal Hysterotomy.

Dr. THEODORE HAULTAIN reported 28 cases in which abdominal hysterotomy was done by the staff of the Royal Maternity Hospital during the last three and a half years. The commonest indication (12 cases) was severe toxic hyperemesis. The others included albuminuria with persistent high blood pressure in the earlier months of pregnancy (5); toxic pyelitis leading to persistent hyperemesis (3); and myocarditis (3). The operation was also done twice in association with myomectomy for degenerating fibroids invading the decidual lining of the uterus, and once each for acute toxic chorea gravidarum, hydatidiform mole and acute phthisis. Only one patient died, a mortality-rate of 3·6 per cent., and this was thought remarkable since more than half the patients were almost in extremis before operation. This rate compared favourably with the 20 per cent. mortality of 25 cases of vaginal hysterotomy for similar indications in the three previous years. The comparative safety of the abdominal route was due to the rapidity and ease of the operation, and to the absence of the severe shock and bleeding sometimes associated with vaginal hysterotomy. In cases with dehydration—a frequent cause of death in toxic cases—the peritoneal cavity could be filled with saline. Furthermore, for suitable patients, sterilisation could be done at the same time, and in cases of hydatidiform mole the growth could be removed completely and with certainty. Induced abortion between the third and sixth month was painful and tedious, especially in primiparæ. So far it had not been found that the operation had any bad effect on future conception. One of the patients had had two children since the operation for hyperemesis in 1927.

Dr. C. D. KENNEDY gave an account of four successful cases of abdominal hysterotomy, two of them for severe pregnancy toxæmia, one for an acute exacerbation of a chronic nephritis, and one for acute chorea gravidarum. The first three were operated on under spinal the fourth under general anæsthesia.

OPHTHALMIC DISEASES IN COUNTY DOWN.—A report to the Down County Council states that there are 529 blind people in the county, 20 of whom are under 16 years of age, and 6 between 16 and 20. The children suffering from external diseases of the eye number 863, 3833 suffer from defective vision, and 620 from squint. Other ailments bring the number of children in County Down in need of remedial treatment up to more than 20,000—55 per cent. of the total.

TUBERCULOSIS CONFERENCE.

LONDON, JULY 3RD–5TH.

THE sixteenth annual conference of the National Association for the Prevention of Tuberculosis was opened by the Minister of Health, who referred to the significant fall in the death-rate from tuberculosis. The unification of public assistance with the health services, he said, would enable the local authorities to visualise the problem as a social rather than an individual one. Without adequate after-care of the patient much of the expenditure incurred in treatment and prevention might be wasted.

Sir GEORGE NEWMAN spoke on the origin and social purpose of the

Local Government Act, 1929.

He traced the development of the Act out of the Reform Bill of 1832, and outlined its relation to tuberculosis. Now, for the first time in history, a public medical tuberculosis service was placed in the hands of one authority, concerned in public health, public assistance, and education. The disease, he said, was essentially connected with such social problems as poverty and housing, and social and sanitary improvements during the last sixty years had produced a remarkable decline in the disease as a whole. The Act made it possible to apply in very many areas the principles of the scheme designed by Dr. Lissant Cox for Lancashire.

Dr. J. PARLANE KINLOCH dealt with those aspects of the Act especially applicable in Scotland. The rate of decline in mortality had been greater, but the total death-rate was still greater in that country than in England and Wales. The new Act had given an impetus to the development of regional schemes of health administration, and institutional authorities and doctors were being organised in a way which would bring the medical profession into a new relationship with the hospitals. The tuberculosis clinic would be brought into organic union with other health service clinics and research would be stimulated.

Dr. NORMAN PATRICK said that attempts were still on foot in Northern Ireland to consolidate the Local Government Acts, following England and Scotland as closely as possible. The greatest difficulty was the coördination of the tuberculosis and maternity and child welfare services.

Councillor G. A. GRIFFITHS said that in practice chief medical officers had to do what their local authorities told them, and thought that an inspection of the workers' pantries would reveal the origin of tuberculosis. In the West Riding of Yorkshire only three kinds of shops kept going to-day: the margarine shop, the American meat shop, and the pawnshop.

Councillor P. MCKENNA urged a subsidy to provide adequate housing for discharged patients.

Dr. W. BOLTON TOMSON warmly supported this suggestion, and paid tribute to the work done at Sheffield in allocating houses to the hospital committee for the use of tuberculous patients.

Councillor G. BRETT said that in Leeds 6 per cent. of all new houses were earmarked for tuberculous families and another 6 per cent. for the prevention of overcrowding, but without a subsidy this only touched the fringe of the problem; the trouble was to find houses at a rent which these families could afford.

Dr. E. E. PREST spoke of the importance of minor tuberculosis, and advocated the treatment of people who were "feeling ill" rather than of people with

shadows in their chests. Early treatment was the only means of ensuring perfect cure; people willing to go to a sanatorium might be exempted from notification.

EFFECT OF THE ACT ON INSTITUTIONAL TREATMENT.

Dr. J. A. WILSON described the Act as a measure of promise rather than of fulfilment. It should remedy the inadequacy of beds which had compelled local authorities to board out patients. To use the new accommodation to the best advantage a new survey of the disease was desirable. There had been important changes in its natural history during recent years: alteration in the age-distribution and the type. The case-mortality at ages over 25 had been markedly reduced in pulmonary tuberculosis, especially in females, and the non-pulmonary forms had shown a very marked reduction in the case-mortality under one year, with a much slower reduction in the 1–5 years age-period. These forms, other than meningitis, seemed to be decreasing in virulence. The highest incidence of the disease occurred in the smaller types of house, and institutional accommodation must therefore be estimated on the assumption that there could be little home treatment. A five-year inquiry in Glasgow dealing with 2500 patients had shown that one bed was required for every five registered cases, in the ratio of 4 male to 3 female beds. The disease had proved to be to a large extent a hospital one, so that the proportion of hospital to sanatorium beds should be 7 to 1, although in both types of institution the turnover was about two patients per bed per annum. For non-pulmonary cases the ratio of hospital beds to registered patients had been 1 : 3·3, equally distributed between the two sexes, but with only one patient per bed per annum. The use of X rays in diagnosis had largely removed the necessity for observation wards, but some provision had still to be made for a group of chronic respiratory conditions in children, usually associated with enlargement of the root glands and seen after epidemics of measles.

Dr. K. J. ACTON-DAVIS said that the problem of non-pulmonary tuberculosis was an entirely different one in children and in adults; in the adult there was nearly always a pulmonary lesion as well, and the prognosis, therefore, was far more serious. It was now generally agreed that the best method of treatment was in special State or State-aided institutions, with after-care in clinics at these hospitals, with the help of the schools. In London the treatment of surgical tuberculosis in children was as nearly perfect as it could be, but in smaller boroughs patients sometimes had to wait for vacancies in charitable institutions. It was among the adult cases that improvement might be expected from the new arrangements. The voluntary hospital was not the place for the treatment of tuberculosis; conservative treatment could not get a fair trial.

Dr. R. S. WALKER said that Paddington had incorporated the poor-law hospital into the tuberculosis scheme some years ago, and the guardians had invited the tuberculosis officer to join their visiting staff. Endeavours were made to induce patients to enter hospital from overcrowded homes for long periods of rest. They were willing to go into a hospital that was near home.

THE GRANT IN AID.

Dr. F. E. FREMANTLE, M.P., who opened a discussion on the effect of the change from percentage to block grant, said that the great drawback of the percentage grant had been that the more an authority spent the more it benefited, and he quoted figures showing the inequitable distribution that had prevailed. The block grant gave local authorities a security which enabled them to establish schemes over a period of years, and was based on the definite principle of need, including the five factors of population, rateable value, unemployment, mileage, and—most important from the tuberculosis point of view—the proportion of children to the population. Under the new system institutions could be pooled and counties would gradually be able to build up magnificent schemes of institutional provision, nursing and health-visiting, and laboratory and consultant services.

Dr. F. J. HENDERSON COUTTS reviewed the discussions which had waged round the problem of the block grant, and said that medical inspection must continue much as before if efficient administration and suitable development were to be secured, but time would be saved in discussing trivial details of expenditure. The percentage grant had undoubtedly acted in the past as a stimulus to development, and there was a certain danger in the inelasticity of an all-round grant.

Mr. H. L. FRASER described the development of tuberculosis schemes in Scotland, and thought that the new system would certainly assist the poorer counties. It was important that non-pulmonary tuberculosis should be treated in a few large centres rather than in many small centres.

Major WALTER ELLIOT said that the Act had been designed to make the local and central authorities partners in health work, and the local authority mainly responsible for expenditure. At the quinquennial revision the expenditure of the local authority as a whole would attract to it a greater revenue; therefore services could be floated up by quinquennial increases from the Treasury. This concession by the Treasury was of the utmost importance. Any system could be made to work by goodwill and public opinion, and in his opinion this Act gave the greatest possible scope to goodwill and enlightened public opinion. We had learnt in the twentieth century the necessity of dealing with a citizen as a citizen and not as a passenger, a parent, a prisoner, or any other one aspect of his civic life. Only along that avenue was it possible to bring home the other great lesson—that failure in public health was failure in economy. To keep a sick man, still more to keep a focus of infection, was much more expensive than keeping a Rolls-Royce. Progressive poor law authorities had grasped this fact before the Act, and had developed large and expensive health services. This showed the relative unimportance of the system of grants. Unified authorities would be able to drive home the economic loss in every department of life.

Alderman DAVID ADAMS thought that the block grant had material defects, as it need not necessarily be expended on public health services. In distressed areas there would be a great temptation to put it to the relief of the rates. Expenses were bound to fall on the local authority, and the quinquennial reconsideration was cold comfort.

Position of the General Practitioner.

Opening a discussion on the relationship of the general practitioner to the treatment of tuberculosis, Dr. G. LISSANT COX said that if the tuberculosis officer were the Cinderella of the public health services, it was doubtful whether the general practitioner was the good fairy or the ugly sister. He did not do nearly as much as he might do in the treatment and prevention of tuberculosis, and his failure was to be ascribed to the conditions under

which he worked, and his training as a student. Coöperation between him and the tuberculosis officer must be effective. He must have time to examine his patients carefully, and he ought to have a special training in tuberculosis, like that provided by the Scottish medical schools. Patients suffering from tuberculosis were rarely seen in general hospitals to-day, and the education of the practitioner therefore called for a close connexion between the tuberculosis dispensaries and the teaching hospital. Moreover, examiners almost always produced cases with old chronic fibroid phthisis, instead of early cases. The tuberculosis officer must be an expert, but no matter how good he was the results of his labour would be meagre if the general practitioner could not play his part in the tuberculosis campaign.

Dr. J. COHEN pointed out that late notification was as often the fault of the patient as of the practitioner, and should be attacked along the lines of educational work by the dispensaries. In large towns home treatment was very seldom possible or advisable, and the sanatorium provided education as well as treatment. Many tragedies followed the return to an overcrowded home, and it was difficult to see how to prevent them with the present housing conditions. A lack of interest in the dispensary among doctors might be due to lack of effort on the part of the dispensary to coöperate with the practitioner. The patient was treated at the dispensary and visited by the nurse, and did not keep in touch with his own doctor. It would be better for him to be seen more often by his general practitioner, who would send periodical reports to the tuberculosis officer. Dispensaries often prescribed medicine when the case should more properly be referred to the practitioner. Local practitioners might be invited to take an active part in the work of the dispensaries, the tuberculosis officer acting as consultant and supervisor. Public education should be one of the main functions of the dispensary. Practitioners would greatly appreciate a clinical report with patients returning to them from sanatoriums.

Dr. WILLIAM BRAND remarked that the insured patient was entitled to treatment for tuberculosis as much as for other diseases, and deplored the fact that patients who ought to be in bed insisted on dragging themselves out to the doctor's consulting-room or the dispensary. With the ascendancy of hygienic habits the cult of the medicine bottle and gallipot would disappear, and domiciliary treatment would become a much simpler problem. At present the two difficulties that constantly confronted practitioners and tuberculosis officers were in the prevention of reactivation when quiescence had been achieved in a sanatorium, and, secondly, in a speedy diagnosis of reactivation. Team-work was the first necessity in an attempt to make domiciliary treatment of much greater advantage than it was at present. The general practitioner could not stand alone, for any of his cases might require the other forms of treatment provided by the local authority —e.g., extra diet, hospital treatment, light treatment, or financial help in obtaining proper food or a separate bed. Moreover, the specially trained tuberculosis officer, equipped with modern refinements of diagnosis, could give great help in the difficult problem of early diagnosis.

Dr. V. J. GLOVER said that in Liverpool as much treatment as possible was given by the general practitioner, and uninsured patients were treated at municipal expense, the doctor being paid three shillings for each attendance. The cost of treatment was £6000 a year, and of medicines £2000 a year per 1000 patients under treatment. The scheme had worked successfully since 1913, and there was no fear that the practitioner would lose a case through notifying it.

Dr. VERE PEARSON spoke of the need for simplifying and improving the teaching of students, and said that tuberculosis dispensaries should be staffed by general practitioners. The great drawback to domiciliary treatment was the economic condition of the home. In Bergen, Norway, general practitioners were given a six weeks' holiday at the public expense to study in sanatoriums.

Alderman TAYLOR strongly opposed treatment by the general practitioner, who, he said, did not know enough about it, while the panel doctor was also far too busy.

Tuberculosis and Education.

Dr. W. L. BURGESS stressed the importance of coöperation and the need for each local representative of the service to have a new and wider outlook. The infection was usually contracted in childhood, but the child had a strong tendency to recover, and environment was an important factor in determining the course of the infection; the education authority, therefore, had a most important part to play. Every school medical officer must have at his service a skilled diagnostician able to recognise the child who required special attention from the tuberculosis department. Intimate contact between the two officials was essential; they should confer daily, and the tuberculosis officer must have free access to the school clinic and the school. Both officers must coöperate also with the nurse who visited the home; the tuberculosis nurse knew a great deal about the homes of the notified cases, but little about other homes or school life; the school nurse knew all about the school but little about the home. There should be more systematic examination of contacts. Continuity of treatment through all ages and in every environment was essential. The nursery school provided an intermediate phase between home and school where the two medical officers could look for fertile soil at a stage when prevention was a certainty. There was now no doubt of the value of open-air schools, but should not every school be an open-air school? It would be wise to assume that every child was a potentially tuberculous child, for modern civilisation made every child a contact. Benefit would be derived from handing over to the school medical officer the responsibility for the care of the pre-school child, and the nursery school must become a recognised unit in the educational system. Education authorities could play an important part in the campaign by supplementing and correcting diet.

Dr. GEORGE MACDONALD said that the open-air school was not merely school in the open air, but a way of life and a system of education and medical treatment. Its dining table should be a factor of educational value, and rest periods before and after the midday meal were very important. In London the tuberculosis officer was part-time school medical officer to the school for tuberculous children, and one of the dispensary nurses was part-time school nurse. The work of the school should include vocational training and after-care.

Mrs. LEAH MANNING described the open-air school at Cambridge and its routine. The morning was given to work and the afternoon to rest and recreative lessons.

THE NURSERY SCHOOL.

Miss MARGARET MACMILLAN described the open-air nursery school which children entered at the age of

two. By a growth and extension of this system she was sure that the hospitals could in time be emptied.

Dr. BRIDIE O'CONNOR said that a striking feature of the MacMillan open-air nursery school, where she was medical officer, was the freedom from catarrhal conditions. Healthy gastro-intestinal and respiratory mucous membranes were a very great safeguard against invasion by the tubercle bacillus. It has been shown that these children, most of whom came from one-roomed homes, acquired increased resistance to disease, and very marked recuperative powers. The pale, flabby, debilitated, rachitic, dull, and apathetic child became sturdy, happy, contented, bright, and responsive. There was a striking absence of complications after measles.

ASSOCIATION OF AMERICAN PHYSICIANS.

ANNUAL MEETING AT ATLANTIC CITY.

THE Association held its forty-fifth annual meeting at Atlantic City on May 6th and 7th under the presidency of Dr. THOMAS MCCRAE, of Philadelphia.

Symposium on Coronary Disease.

Dr. O. KLOTZ and Dr. W. D. M. LLOYD (Toronto) reported 44 cases of partial or complete coronary occlusion verified at autopsy. In 26 there was sclerosis with narrowing but not occlusion, and there were 18 cases of thrombosis, all accompanied by sclerosis. The commonest location of the sclerosis was in the descending portion of the left branch; next in the left coronary; and last in the right coronary. Sclerosis obstructing the orifice was more common in the right than in the left coronary. The thrombotic process appeared to be secondary and took place by dilatation with development of a thrombus. Under normal conditions anastomosis was free between the right and left coronaries. When the left coronary was involved and there was already a degenerative process on the right much more severe damage to the myocardium resulted. When only the left coronary was damaged the myocardium remained competent, anastomosis being enough to maintain circulation.

SYPHILIS.

Dr. A. S. WARTHIN (Ann Arbor) said that in 1675 autopsies in his laboratory in Michigan during 25 years there were 408 males and 86 females showing active syphilitic lesions in the aorta or central nervous system. Between 1910 and 1919 the average was 43 per cent. In the years 1919–29 332 cases of syphilis came to autopsy and of these 172 had coronary sclerosis. There were 55 cases of coronary syphilis and 5 cases of coronary thrombosis. In both decades it was found that the incidence of coronary sclerosis was a little higher in autopsies on syphilitics as compared with non-syphilitics. The figures showed that death occurred ten years earlier, and sudden death was commoner, among the syphilitics.

PROGNOSIS IN CORONARY THROMBOSIS.

Dr. LEWIS A. CONNER (New York) reported on 287 cases of coronary thrombosis, 243 men and 44 women, of whom 117 were private patients. Antecedent disease in 274 cases was as follows: arterial hypertension, 93; syphilis, 39; diabetes, 28 (total 58·3 per cent.). The age of the patients at first attack was as follows: Before 35, 3 per cent.; 41–45 years, 11 per cent.; and 50–60 years, 22 per cent. From 61–65 there was a very sharp drop—that is, 75 per cent of all cases occurred before the age of 61. As regards sex, it was found that the women lagged behind the men in the early cases, but a large proportion of first attacks in women occurred between 55 and 60 years. Of the 287 cases, 117 (45 per cent.) were still alive, and 28 had been lost sight of. Forty-six had died in the first attack; 89 were well after the first attack, and 28 of these were well up to the second attack, when they died. The total duration of life varied from 3 months to 17 years after the first attack, and was grouped as follows:—

	Cases.		Cases.		Cases.
3 months ..	109	4 years ..	40	9 years ..	4
6 ,, ..	101	5 ,, ..	25	10 ,, ..	4
1 year ..	88	6 ,, ..	17	11 ,, ..	3
2 years ..	65	7 ,, ..	15	12 ,, ..	2
3 ,, ..	49	8 ,, ..	7	17 ,, ..	1

The relation of prognosis to severity of symptoms was as follows: 68 per cent. died with very severe attacks; 10 per cent. died with mild attacks; 31 per cent. recovered from very severe attacks; 43 per cent. recovered from moderate attacks; 26 per cent. recovered from mild attacks. Thus it seemed that very severe attacks are very often recovered from. In regard to previous symptoms, 38 per cent. had had symptoms and 62 per cent. had had no symptoms before the first attack. The interval between the first and second attacks in half the cases was less than one year, and in the others it was from 3 months to 18 years. In some cases there were more than two attacks. One patient had 7 attacks before he died. Embolism occurred in 42 cases. An electrocardiogram was made in 151 cases; 21 patients had normal tracings, of whom 14 are living and 7 have died. There was T wave change in 37. With auricular fibrillation or bundle branch block the prognosis was very bad.

These studies, said Dr. Conner, suggested that coronary thrombosis was a disease of early middle life. If the underlying condition was arterio-sclerosis, perhaps some of the changes were occurring in other organs. Diabetes might be caused by thrombosis of the pancreatic artery, and renal embolism might be due to thrombosis.

CHANGES IN ELECTROCARDIOGRAM.

Dr. R. W. SCOTT (Cleveland) reported (with H. S. FEIL, L. N. KATZ, and R. A. MOORE) experiments on the electrocardiogram in dogs. Under barbital anæsthesia the ramus descendens of the left coronary artery was tied at various levels; the inferior vena cava was also ligated for five minutes. Ligature of the vena cava gave negative results, because the collateral circulation was extremely abundant. If the coronaries were tied the chart showed the influence of extrasystoles and tachycardia. Ligature of the descending branch of the left coronary for 30 minutes caused no marked R–T deviation, but further impairment of the vena cava produced R–T deviation as seen in coronary thrombosis. Development of an abnormal mechanism, such as tachycardia or extrasystoles, produced deformities of the R–T tracing typical of coronary occlusion.

Dr. E. P. CARTER (Baltimore) said that in the past few years there had been an attempt to use the electrocardiogram in coronary disease to localise the site of the insult as well as the extent of the myocardial damage. Not enough emphasis had been laid on the duration of the trauma or on a properly correlated clinical diagnosis. Smith's early experimental work had laid great stress upon the ligation of the coronary vessels, but it was now known that heat and cold could easily upset any phase of the ventricular

complex. Lesions resulting from interference with the coronary circulation were due to ischæmia or local anoxæmia, and the significance of the changes in the electrocardiogram depended on the rate at which the lesion developed. The perturbations of the end-phase of ventricular work represented the degree of anoxæmia present in the myocardium. Dr. Carter wanted to emphasise the significance of lesions leading to diffuse myocardial disease, as distinct from those of the septum and main stem. There were lesions due to toxic changes, and also to systemic change as in myxœdema, and in such cases changes in the end-phase must be interpreted in the light of the other clinical findings.

Discussion of Symposium.

Dr. JAMES B. HERRICK (Chicago) thought the question of coronary obstruction was very far from settled. It was not always possible to interpret the electrocardiogram. There was a great deal of difference clinically between acute transitory partial obstruction and gradual permanent complete obstruction. The electrocardiograms of both forms deserved more extended study before their significance could be stated positively.

TWO EFFECTS OF OCCLUSION.

Dr. EMANUEL LIBMAN (New York) spoke of two further effects of coronary artery occlusion. The first was its influence on the papillary muscles, especially the posterior muscle on the left side. This was supplied by the descending branches of both coronary arteries and these were frequently diseased. Fibrosis and atrophy not infrequently took place in the muscle and might lead to chronic dilatation of the heart. As far as he knew this condition had not hitherto been described. The other effect of coronary artery disease he had in mind was aneurysm of the left ventricle. In 1919 he had outlined a method of recognising aneurysm involving the anterior wall of the left ventricle, and employing that method he had suspected its presence 44 times in his private practice during the past three years—i.e., in 27 per cent. of all cases in which he suspected the presence of marked coronary occlusion. Klemperer, reviewing the figures of the past three years in post-mortem examinations at Mount Sinai Hospital, found that 50 per cent. of all cases of marked occlusion revealed an aneurysm somewhere in the heart and that the figures for aneurysm of the anterior wall of the left ventricle was 38 per cent. Another indication of this condition was a gallop rhythm of anapæstic type, heard best at the left border of the sternum low down. He found that Réné Marie had made the same observation, but he had not mentioned the important fact that the gallop rhythm should be looked for while the patient was lying down. It might be absent on standing.

Dr. Libman was not convinced that coronary thrombosis was simply a part of the arterial disease, and he believed it was essentially part of a general condition. The patients had often suffered earlier from thrombosis of the arteries of lower limbs or the brain.

Dr. CONNER said that, being familiar with Dr. Libman's views concerning the frequent association of other arterial thromboses with coronary thrombosis, he was somewhat surprised to find that in only two of the cases was there a record of other arterial involvement. There were four cases in which thrombosis of one or more large veins occurred after the cardiac attack; but in these it would be difficult to feel sure that they were not dependent merely upon the circulatory impairment.

PROGNOSIS AND TREATMENT.

Dr. W. S. THAYER (Baltimore) said that coronary prognosis was rather better than was thought at first, and was the key to treatment of the condition. Here the practitioner could do a great deal. One of the most important things that Osler taught was the necessity of rest under treatment of all sorts of maladies, but in coronary disease it was vital for two reasons: first because the patient's heart muscle often needed rest, and secondly because he needed to be adjusted mentally to his condition. This could only be done through a long period during which the doctor was labouring hard to make the patient understand his condition. The only way to train him was to put him to bed for many weeks. If he could be shown what could be done by rest and massage he could be trained so that he would live for many years.

Dr. ROBERT L. LEVY (New York) said that the more one took into account the pathological basis of the causation of cardiac pain, the less often was one inclined to speak of it as angina pectoris. He had been studying a group of patients suffering from "mild types" of coronary thrombosis. The severity of the onset varied, but the cases were mild in the sense that they made an unusually rapid recovery. From the point of view of the prognosis this was important, for it was found that it was not so much the intensity of the initial symptoms as the rate of recovery which served to indicate the ultimate outcome. The electrocardiographic changes observed were those commonly associated with acute coronary obstruction. In some of the cases a second attack followed the first after an interval of four or five years, and in one instance proved fatal. It was often difficult to persuade these patients to remain in bed for more than 24 hours because of the rapid disappearance of discomfort.

Dr. WARTHIN said that the essential pathology in all cases of angina pectoris was that of progressive anæmic infarction and fibrosis. The same pathology was found in the cases of angina having a previous history of syphilis. In these the affection was primarily a coronary one, with resulting infarction. In the cases of sudden death without a previous history of angina the pathology was chiefly that of a diffuse interstitial fibrosis, and not scarring due to infarction.

Dr. JOSEPH T. WEARN (Cleveland) agreed about the necessity for rest in coronary sclerosis. He had had several cases of complete occlusion of both coronary arteries as a result of syphilitic aortitis, and a great many cases where sclerosis had practically closed both coronary orifices. It was remarkable to note that in many of these cases the patient had had few, if any, symptoms of heart disease. Sclerosis was a slow process and syphilitic aortitis was a slow process. Both required months probably to close the coronary arteries. This lapse of time allowed the Thebesian circulation to enter the picture and take up its new duties as substitutes for the arteries. It was well known that many patients will become free from anginal attacks after prolonged rest when other methods have failed.

EXPERIMENTAL CORONARY OCCLUSION.

Dr. F. M. SMITH (Boston) pointed out that some cases of coronary occlusion were hard to diagnose by ordinary clinical means and in these electrocardiography might be of great assistance. The changes were frequently missed by not taking a curve early after the accident, or might not be recognised from

one record. He was much interested in Dr. Scott's finding that ligation of the descending branch of the left coronary might not be followed by alteration in the electrocardiogram unless it later increased the work of the heart. In his own work, the changes in the electrocardiogram were generally proportional to the extent of the disturbance of the coronary circulation. Ligation of the circumflex branch of the left coronary artery was thus followed by the greatest alteration in the electrocardiogram. The fact that Dr. Scott did not ligate the vein might make some difference in the results. The extent of the collateral coronary circulation of the dog varied greatly, and this must be taken into consideration. It would seem, however, that the ligation of either of the larger branches of the left coronary artery would produce changes in the electrocardiogram if enough disproportion was induced between the coronary circulation and the heart load.

Dr. W. G. McCALLUM (Baltimore) drew attention to the anatomical distinction between closure of the right and left coronaries. The right coronary was of greatest importance. On examination of the open artery the posterior half of the septum of the wall of the right ventricle behind the mitral valve was thin. It could be dropped into the cavity. In the left coronary, on the other hand, obstructive necrosis extended it at the narrow part of the septum at the apex, which caused aneurysm. The process extended through the right ventricle and gave rise to embolism of the pulmonary artery. The distinction was extremely sharp when seen at autopsy.

Dr. NORMAN M. KEITH (Rochester, Minn.) said that Barnes, Mann, and Markowitz of Rochester were reinvestigating the electrocardiographic changes resulting from ligation of various branches of the coronary arteries in dogs. It had been found that these changes did not parallel exactly the tracings obtained in man after occlusion of analogous vessels. On the other hand, it did appear that ligation of a branch of the right coronary artery producing infarction in the right ventricle caused electrocardiographic changes characteristically different from those obtained on ligation of the left coronary artery.

A NEW TECHNIQUE.

Dr. WILSON (Ann Arbor) said that the electrocardiographic changes associated with infection of the myocardium were related to the monophasic responses obtained in the physiological laboratory by placing one electrocardiographic electrode upon an uninjured and the other upon an injured region of the heart's surface. In the mammalian heart monophasic responses persisted for a few minutes only, although the electrocardiogram remained abnormal for a much longer period whose exact duration was uncertain. After the injured muscle died, of course, it no longer exerted an effect upon the electrocardiogram. During the last year new methods of studying the electrocardiogram had been devised which he hoped would throw new light upon interpretation. By taking præcordial leads, as well as the usual three leads, much additional information concerning the spread of the excitation process over the heart and also, he believed, regarding the final deflection of the electrocardiogram might be obtained. It was hoped that much information might be gained from such leads in coronary thrombosis. By measuring the area under QRS and also under T the normal relation between T and QRS and the variations of this relation in disease could be studied. By this method abnormalities of T might be recognised and studied quantitatively even when they were associated with changes in QRS—that is to say, he believed it possible to determine whether a given abnormality of T was or was not dependent upon an associated abnormality of QRS.

REVIEWS AND NOTICES OF BOOKS

Cottage Hospitals.

By Major F. M. DU-PLAT-TAYLOR, M.Inst.C.E., JOHN COLLERIDGE, F.R.I.B.A., and J. J. ABRAHAM, C.B.E., D.S.O., M.D., F.R.C.S. London: Ernest Benn, Ltd. 1930. Pp. 99. 12*s.* 6*d.*

THE authors of this book—an engineer, an architect, and a surgeon—have pooled their professional experience for the benefit of local authorities and others who may have to build and equip cottage hospitals. Obviously, within the compass of a small book, it has not been possible to deal at length with such subjects as administration, design and construction, X rays department surgical equipment, general equipment, still less with the cottage hospital as part of the voluntary hospital system. But since the style is terse, and padding is absent, they have contrived to supply a considerable amount of information. Cottage hospitals do not differ materially from the larger general hospitals. They are, in fact, models on a smaller scale of these institutions, but established in rural districts on much simpler lines with a matron as superintendent. They are primarily surgical hospitals, and their work has undoubtedly been much affected by the new conditions arising from the increase in motor accident cases. It is necessary, therefore, that such hospitals shall be designed and equipped for the purposes of a hospital; any offer of an existing building should be very carefully considered, since often it will be found that the cost of conversion is more than the cost of a new building designed for the purpose, and therefore more satisfactory.

Thirty-six pages are devoted to design and construction, a most important section of the book. Certain parts of the building are essential in all hospitals irrespective of size. For instance, corridors cannot be reduced in size, for, though the passing to and fro is much less than in a large hospital, the length of stretchers which must be wheeled out of rooms and turned remains the same. It is sometimes possible, however, by providing recesses at certain points for turning purposes to reduce the general width of corridors.

Apart from bed accommodation and the necessary auxiliary utilities, no cottage hospital can be considered complete unless it contains a properly equipped X ray department and an operating theatre, both designed on modern lines. The authors stress the importance of these departments, and it is, indeed, unfortunate that the majority of cottage hospitals are not yet so provided. Lack of funds is undoubtedly the reason, but having regard to the increasing number of major operations now being done in cottage hospitals, these two departments are really essential. Plans of three typical hospitals are appended, and these will be of especial interest to hospital committees. This book will interest those who have in mind the establishment of cottage hospitals, or indeed hospitals of medium size.

Radium and Cancer (Curietherapy).

By DUNCAN C. L. FITZWILLIAMS, C.M.G., F.R.C.S., Senior Surgeon, St. Mary's Hospital, Paddington. London: H. K. Lewis and Co., Ltd. 1930. Pp. 172. 12*s*. 6*d*.

"Radium and Cancer" is an attempt to outline Mr. Fitzwilliams's own experiences in radium therapy, the amount of the element at his disposal being limited; at the same time other methods than his own are discussed. The book opens with a very short historical and physical review, followed by a clear description of the various types of applicators, both of the element and emanation; the author prefers local implantation with needles or surface irradiation with a columbia paste applicator. Each organ liable to be attacked by malignant disease is considered in turn and the advantages of the various methods of approach are discussed together with an exposition of the author's technique and a few case-histories. The chapter on uterine carcinoma has been written by Dr. Malcolm Donaldson and is arranged on the same general lines as the rest of the book, but it has the advantage that other methods of treatment are discussed in greater detail, and statistics revealing the results of these as well as of his own methods are given.

Throughout the book Mr. Fitzwilliams describes the dosage in milligramme-hours, but in certain places he gives the expanded multiplication form (amount of element × number of days × number of hours), which is preferable, as it defines the all-important time factor. The book gives the impression of being somewhat premature; it might have been more profitable to wait until the results of the methods employed could be given. No statistics (save Dr. Donaldson's) are supplied, and the majority of the cases (40 in all) are of too recent date to estimate their success. No mention is made of post-operative care, follow-up schemes, or the treatment of recurrences. Mr. Fitzwilliams, following the French nomenclature, uses "Curietherapy" as a sub-title. This seems an arguable term. The Curies played no part in the original discovery of radium's biological properties (they have already gained eponymic fame in the millicurie, a more pleasantly sounding word). Further, were the term generally adopted in this country, it might suggest to the lay mind that radium was a "cure."

The book is fully illustrated, and all the diagrams demonstrating the position of needles in relation to the growth are excellent both in clarity and simplicity.

Athletics in Education.

By JESSE FEIRING WILLIAMS, A.B., M.D., Professor of Physical Education, Teachers' College, Columbia University; and WILLIAM LEONARD HUGHES, A.M., Professor of Physical Education, de Pauw University, Indiana. London: W. B. Saunders Company. 1930. Pp. 414. 14*s*.

IT is the aim of the authors "to draw attention to the tremendous educational possibilities of athletics properly conducted." Most of the book—actually two-thirds—deals with suggestions for the conduct of athletics; and an average reader confronted for the first time with so complex a system will be bewildered and amazed. In this country we are accustomed to treat the organisation of our sport in a far more casual fashion. There is no official, whether qualified medical man or retired athlete, who aspires to the title and position of director of physical education; but any such duties are usually gratuitously assumed by an active member of a team or some other good natured self-sacrificing amateur. Whether or no the elaborate scientific administration which this book describes would produce better results in this country, it is fairly safe to say that our tradition and temperament would always be antagonistic to its institution. Regarding themselves as ranking in dignity, responsibility, and service with other teachers, the authors justly demand appropriate recognition upon boards of control in which education in all its aspects is directed. To speak in appropriate language, one senses the atmosphere of personal grievance in the references to prejudices of old times persisting to this day and leaving the professor of physical education still socially *persona non grata*.

This work is essentially written by Americans for Americans. A bibliography of 85 pages, containing nearly 1000 references, includes no British and hardly a European contribution. Titles are suggestive of the part played by athletes in the social system; Are American athletics boss-ridden? Keep politics out of athletics; Are athletic coaches overpaid? Athletics are not a necessary evil; Sport as a socialiser. Diagrams of boards of athletic control are almost unlimited in comprehensiveness. Radiating from the central responsibility are such diverse branches as education, finance, hygiene, publicity, politics, and so forth. There is even provision for the "cheering section" with instructions when distinction must be drawn between extreme partiality and the more sportsman-like possibilities which such a section might display. The book will have only an abstract interest to students in this country. Our athletes could never be educated to accept such a degree of officialdom as the American system implies. Anyone who has had the experience of conducting an athletic programme single handed or with the aid of two or three inexperienced assistants must wistfully, if perhaps cynically, receive the information that to run a track meet a force of at least 50 officials is essential. A chapter on the medical control of athletics is excellent if rather condensed.

Shorter Convalescence.

By Lieut.-Colonel JAMES K. MCCONNEL, D.S.O., M.C. London: William Heinemann, Ltd. 1930. Pp. 132. 5*s*.

THIS is a small book with a large title. But it is, as Sir Robert Jones says in a prefatory note, "a valuable contribution to the physiology of muscular action and its relation to convalescence." There is no doubt that the exercises which the author recommends as appropriate in a large number of cases to the convalescent would minimise the period of weakness that must ensue after debilitating disease. A brief section entitled Types of Bed Exercises gives exactly the kind of information, where common types of recuperating patients are in consideration, which is required by the medical practitioner. The author claims that such exercises have an important effect on the mental outlook of the patient and thus aid his recovery; for in the performance of these manœuvres he realises that he can do something for himself, and introspection is diverted into useful channels. Moreover, the strengthening gradually of unused muscles preparatory to their full exercise after convalescence appeals to logical sense. Colonel McConnel has benefited by attachment to St. Thomas's Hospital and is able to quote clinical experience that this type of exercises has produced good results in patients of all ages, who, moreover, take a keen interest in carrying them out.

THE LANCET.

LONDON: SATURDAY, JULY 12, 1930.

HOUSING AND CHILD HEALTH.

THE House of Commons appears to be divided in its mind as to whether less houses are being built in 1930 than in 1929; Mr. KINGSLEY WOOD and Mr. E. D. SIMON contending that this diminution has occurred, Miss SUSAN LAWRENCE assured them that, though State-aided houses have declined in number, more houses are being built by private enterprise. Everybody seems to agree that the houses erected by public authorities are too expensive for the people most in need of them, and that our urgent requirement is to provide accommodation more within the paying capacity of the tenants who suffer from the heavy burden on their earnings. The type of dwelling to be supplied merits serious thought. The ordinary citizen is sometimes inclined to wonder for whom houses in this country are planned. Speaking at the National Conference on Maternity and Child Welfare held at Friends House from July 1st to 3rd, Mrs. SOMERVILLE, of Edinburgh, said that the vision behind the Housing Acts had been a desire to render possible better conditions of family life. Yet Mr. NEVILLE CHAMBERLAIN and Sir JOHN ROBERTSON both asserted that the needs of the younger generation are largely overlooked by those charged with the design and lay-out of houses, while Mrs. BARTON, of the Women's Co-operative Guild, was convinced that the last person to receive consideration when house-building is in question is the mother and housewife. Tenements and flats, if well-planned, have certain advantages, though Sir JOHN ROBERTSON would like to restrict them to families where there is no child below the age of 8 or 10 years; the architect of the St. Pancras House Improvement Society objects to the sky-scraper partly because, he says, "it has been found that children born in the upper storeys never come down to earth at all until they are 4 or 5 years old." A pertinent criticism was offered to the Conference referred to by Mrs. MAILLARD, of Penarth, who said that a local council, having discovered what it deems a satisfactory type of house, proceeds to erect all its houses on the same pattern, with the result that one side of the road is properly planned, and on the other both living-room and larder have the wrong aspect. This is an obvious difficulty to constructors, who none the less should find the ingenuity to get over its grosser features.

There is general agreement as to the deleterious effect upon child life of unsatisfactory living conditions. When, as medical officer of health of Birmingham, Sir JOHN ROBERTSON made his careful analysis of infant deaths dividing the city into zones, he found the infant mortality-rate rising by leaps and bounds as he progressed from the outer ring to the centre, where houses are both more closely packed together and more densely occupied. Upon analogous lines valuable evidence was forthcoming on the part of Mrs. SOMERVILLE, who for more than 20 years has been supplying to the Health Department fortnightly reports on the condition of babies born in one- and two-roomed dwellings in Edinburgh. Her investigation has included 30,000 infants, and the conclusion to which she has been led is that overcrowding is one of the most serious adverse forces against which child life has to contend. She made out an exceedingly strong case for placing the overcrowded family on the same level as the family living in a house condemned by the sanitary inspector. There is something strangely anomalous about the position when dwellers in condemned houses become an object of envy to their neighbours. Yet this can hardly fail to be the case when the dispossessed family is eligible for a Council house at an exceptional and uneconomic rent, while the family whose health may be suffering more as a result of overcrowding has no redress, and can only live in a Council house if the full rent can be afforded. Mrs. SOMERVILLE drew a vivid contrast between the 5000 condemned and the 1200 overcrowded houses in Edinburgh. Tenants of the former are being reinstated in Council houses consisting of two rooms and a scullery with individual bathroom and lavatory, at 5*s.* 11*d.* a week, or 7*s.* 6*d.* with an additional bedroom. On the other hand, she has personally applied, times without number, for families suffering acutely from overcrowding, only to be told that there is no rebate available under any Act of Parliament for such cases.

The problem is insistent all over the country, and voluntary housing associations formed for the purpose of tackling it, in small measure and in different localities, are arising in growing numbers, while those of older standing are constantly adding to their achievements. In Edinburgh 18 houses built by the Welfare Housing Trust were opened by the Secretary of State for Scotland last month. These houses consist of a large living-room and good kitchenette, three bedrooms, and an upstairs bathroom and lavatory, and they are let to families with four or more young children at a rent of 8*s.* 6*d.* a week, including rates. A playground has been provided, and each house has a fair-sized piece of ground of its own. It is hoped that useful data may be collected by keeping a careful survey of young children removed from one- and two-roomed houses to these better conditions. Fresh activity is reported from the Thistle Property Trust, Ltd., of Stirling, from Church Army Housing, Ltd., the St. Pancras House Improvement Society, and other bodies with similar objects, though it is distressing to read in a recent account from Manchester that "the rehousing of slum-dwellers is a problem that Manchester has not yet been able to tackle, except in the case of one small slum

clearance in 1923." All these schemes are giving fruitful help, but it is hard to endorse the opinion expressed by Lord BUCKMASTER in the House of Lords that voluntary aid is by far the most potent and important agency for the reconditioning of slums. When all successful voluntary ventures are put together they relieve no more than a fraction of the lower-paid wage-earners for whom better living conditions are an urgent hygienic necessity, to say nothing of the moral and social implications. The report on Housing Conditions in the Borough of Paddington, issued at the end of March by the Westminster Survey Group, frankly stated that :—

> The provision of industrial houses in Paddington on an economic basis is out of the question, and the task of the borough council is impossible of fulfilment unless and until public opinion accepts, not only in theory but in practice, the position that they must be built with public money and let at uneconomic rents—the deficit being defrayed either by the rates or by the taxes.

The statement frequently made with confidence and accepted apparently without misgiving—that the ratepayers' money must on no account be used for experimental work—explains why many of our vital social services have been initiated by volunteers, later to be assisted or adopted by the State when their value has received the unequivocal appreciation of the public. There is, however, some justification for the opinion that the usefulness of providing decent homes at a low rent has now been sufficiently demonstrated to lift the endeavour beyond the stage of experiment. The rehousing of the very poor is essentially a health question, and the suggestion of Dr. P. S. BLAKER, medical officer of health of Dudley, that the allocation of available houses should, under proper safeguards, be placed in the hands of local health committees is sound.

CORONARY THROMBOSIS.

AFTER long neglect in this country coronary thrombosis is at last beginning to arouse the interest it deserves. The description given by Dr. JOHN PARKINSON and Dr. D. EVAN BEDFORD [1] in 1928 brought its clinical features clearly before the profession, and in Dr. JOHN COWAN'S St. Cyres lecture, published last week, we have a further stimulus to study and research. He says that by far the commonest cause of myocardial fibrosis is interference with the blood-supply through the coronary arteries, and where this is sudden or complete the result may be a severe attack of anginal pain. Recovery from occlusion of a coronary artery was until recently considered rare ; the condition was looked on as a common cause of sudden death, although seldom identified outside the post-mortem room. But Dr. LEWIS A. CONNER'S report to the Association of American Physicians, as reported on p. 83, puts a different complexion on it. Of his 287 patients 45 per cent. are still alive and one of them has survived 17 years. Since in these cases prognosis is of the first importance his figures are noteworthy.

Knowledge of the electrocardiographic changes in coronary thrombosis is still sketchy, and it is not yet certain whether it will ever be possible to be sure which branch of the coronary artery is involved. It is now recognised that the changes shown in the electric tracing described primarily by H. E. B. PARDEE, and later by F. M. SMITH, J. T. WEARN, and others, are by no means always present ; in fact no changes at all may be noted after infarction. At the meeting in Atlantic City Dr. SMITH pointed out, however, that such changes are often missed because the patient is not examined soon after the accident or because only a single record is taken, and Dr. WILSON reported that a precordial lead gives much additional information about the spread of the excitation process over the heart.

Dr. HAROLD J. STEWART has attempted to correlate clinical and pathological findings by detailed study of individual cases.[2] In cases of occlusion of certain branches of the coronary arteries he tried to link up his findings with those of PARDEE, SMITH, and others, but was unable to do so except perhaps in occlusion of the circumflex branch of the left coronary, where a decrease in amplitude of the QRS complexes was observed. STEWART endeavoured to demonstrate the value of an accurate detailed record of a particular case as a means of correlating signs and lesions, but the difficulties of such correlation are many. As Dr. COWAN points out, J. S. CAMPBELL'S stereoscopic radiograms show how much the coronary arteries vary in distribution, and if the blood-supply from any part may be derived from different arteries the results of occlusion can hardly be constant. Moreover, as Dr. E. P. CARTER remarked in the discussion, the significance of the changes in the electrocardiogram depend on the rate at which the lesion develops. Nevertheless, an attempt should be made to collect cases where specific statements are made about the occurrence of pain and the exciting cause, and where information is available about the presence or absence of fever, leucocytosis, and friction rub, changes in the electrocardiogram, and detailed autopsy findings. Such records may make it possible to reach definite conclusions about the use of the electrocardiogram as an indicator of the site and extent of myocardial damage.

DENTAL RADIOGRAMS.

THE articles in THE LANCET of last week and in this issue by Mr. BOWDLER HENRY on the interpretation of dental radiograms, and the admirable illustrations which accompany them, deserve to be studied carefully by all practitioners. Even the dental surgeon, familiar though he may be with the technical aspects of the subject, is likely to learn something from the lucid descriptions of the radiographic appearances of the patho-

[1] THE LANCET, 1928, i., 4.

[2] Amer. Heart Jour., 1929, iv., 393.

logical conditions of the teeth and jaws. The doctrine of focal infection has brought dental sepsis into the limelight as a probable cause of many diseases, and has provided the doctor with a new remedy for intractable conditions which he he is eager, sometimes too eager, to apply. It has become a common practice among doctors to send patients to have the teeth radiographed. If the radiograms and the reports which accompany them seem to suggest the existence of infection in the teeth, then the patient is referred to a dentist for the appropriate treatment. This order of procedure has brought with it some unhappy results. Radiograms have their fallacies, as Mr. HENRY has well shown, and these fallacies are increased if the radiograms are technically imperfect. Their interpretation requires special knowledge of the anatomy and pathology of the teeth and jaws. The reports on a set of radiograms ought to be guarded even if the radiologist has special dental training, for as Mr. HENRY has aptly put it, "the radiogram is only one link in the diagnostic chain." Every dentist is familiar with cases in which the radiogram had provided evidence of dental infection not otherwise discoverable; he also sees cases in which the radiogram may be relatively favourable while the clinical evidence provides clear proof of an infected condition. A report made by a radiologist not specially versed in dental pathology may be very misleading. Among dental surgeons it is a commonplace of conversation, not often expressed in print, that radiographic reports in general have little value, though brilliant exceptions occur. Given a good set of radiograms, the dentist generally prefers to make his own interpretation of them, and he alone, as a rule, has the wide experience which entitles him to do so correctly. Mr. HENRY's articles are not intended to provide medical practitioners at one stroke with sufficient knowledge to interpret dental radiograms for themselves, to discriminate between conditions which are harmless and those which are not, to detect fallacies due to technical errors, and anatomical marks such as foramina simulating pathological lesions. Indeed, any doctor who takes upon himself the responsibility of passing judgment on the teeth and referring the patient to the dentist to act as executioner is likely to make serious mistakes, and, moreover, he puts members of the dental profession in a false position. The final assessment of the dental condition must remain the function of the dentist, though coöperation is necessary when a decision has to be made on the treatment appropriate to the particular patient of any dental sepsis which may exist.

There has been a widespread tendency both by doctors and dentists to assume that all areas of bony rarefaction round the apices of dead teeth are of equal importance and provide clear evidence of focal infection calling for drastic treatment. It is now beginning to be realised that this may not always be so, and that the presence or absence of sclerosed bone has considerable significance. The view originally put forward by WESTON PRICE, that the granuloma represents a barrier put up by the tissues against an infection in the tooth, and that it is "a periapical quarantine tissue," is gaining ground. Both the infection and the resistance are variables. A granuloma which at one time may be harmless because the quarantine is sufficient to hold the dental infection in check, at another time may be a danger because either the infection has increased or the resistance has diminished. Given a well-defined rarefied area with well-marked sclerosis around it, then, according to PRICE, the granuloma, though a potential source of danger, may not always be an actual one. Here lies the importance of studying the minute and intimate bone structure, which is only possible in radiograms of high technical quality. The days are passed when a hasty glance at a set of radiograms was enough to condemn or exonerate the teeth. As Mr. HENRY points out, a radiogram requires careful study under proper conditions of illumination and magnification by one who has knowledge of the structure of the teeth and jaws.

It must be admitted that the views of PRICE and his followers are not proven; they represent a working hypothesis which has much to support it, and for the present, at least, may be accepted. Unfortunately, there is still insufficient correlation between radiographic appearances and the morbid histology and bacteriology of the jaws, for the technical difficulties of associating all these findings in any given case are very great. At the present time the dentist may hesitate to allow teeth which have obviously been infected at some period to remain in the mouth, though the presence of a degree of sclerosing osteitis may suggest that the tissues have reacted successfully to the infection. In a serious condition, where the elimination of all discoverable infection is important, it may be wiser to regard all teeth with radiographic changes at the apices as sources of danger which should be dealt with drastically. But there is good hope that as our knowledge increases it may become possible to discriminate more certainly between dental lesions which are relatively harmless and those of high pathogenicity, and in this way to check the slaughter of functioning teeth which is now going on.

A point of great importance well brought out in Mr. HENRY'S articles is that infection may exist in the edentulous jaw. It is most important that a complete radiographic examination of the jaws should include the edentulous areas and that the absence of teeth should not be looked upon as making unnecessary a radiographic examination. The saw-like or feather-edge appearance of the alveolar border sometimes seen in edentulous jaws is a condition familiar to most dentists, and was recently described in THE LANCET by Dr. J. D. KIDD.[1] Not only does this residual infection lead to difficulty in the successful adaptation and wearing of dentures but, as Mr. HENRY has shown, it constitutes a focus of infection the more sinister because it is so likely to be overlooked.

ANNOTATIONS

CONAN DOYLE.

By the death of Sir Arthur Conan Doyle the medical profession loses a colleague whose name, though not for directly medical reasons, is more widely known throughout the world than that of any other member of the medical profession. Not even the Corpus Hippocraticum, with over 2000 years' start, has been sold in such profusion as the various volumes in which Sherlock Holmes appears; and though it is an open secret that Doyle regretted the way in which the popularity of the great detective had overlaid his creator's other claims to recognition as a man of letters, it is very real fame to have invented an eternal figure in fiction. Conan Doyle, who was born 71 years ago, was educated at Stonyhurst, and graduated in medicine in the University of Edinburgh in 1882. He practised for a time as a doctor at Southsea, made an expedition to the Arctic regions, and for a period aspired to the position of a specialist in ophthalmology in London but without obtaining a post at any hospital. He has recorded his experience in the neighbourhood of Cavendish-square as being made up of "a waiting room and a consulting room, where I waited in the consulting room while no one waited in the waiting room." This outcome of his ambitions made him turn to fiction as a means of livelihood, several varied excursions in that direction already having proved profitable. Among these early books was an admirable historical novel, "The White Company," published exactly 50 years ago. The knowledge and grip here displayed made it certain that works of a similar kind from his pen would have been successful, but the instantaneous popularity of the Adventures of Sherlock Holmes, which appeared as a serial the following year, exercised an influence over his literary career from which he constantly attempted to break away. "The Adventures" were at different times followed by "The Memoirs," "The Return," and "The Case Book," while in other well-constructed novels Holmes is the protagonist. Between their publication, however, there came from his pen an excellent novel of Regency days, other historical novels, and two books of distinctly medical interest—namely, "Round the Red Lamp" and the "Stark Munro Letters." Professional developments, altering the conduct of medical practice, may have made these two last books no longer topical, but they will repay reading for their observation of much that occurs now and much that lately formed routine. During the South African War Conan Doyle returned to the exercise of his calling and rendered the country excellent service; for he was senior physician to the Langman Field Hospital, while on the cessation of hostilities he wrote a history of the war in which, by tracing back the causes and reflecting on the conduct of the struggle, he attempted to place the true facts of the war before Europe. This book was translated into a dozen foreign languages and a large number of copies were distributed gratuitously, while the author received the honour of knighthood.

In the latter part of his life Conan Doyle threw himself with vigour into the promotion of the cause of spiritualism, and while many must have considered that his vivid imagination played too large a part both in his theories and in his acceptance of facts, no one doubted his deep sincerity.

TUBERCULOSIS IN EVERYDAY PRACTICE.

By a slow process of attrition the general practitioner has gradually been shorn of his opportunities in all those social diseases which for one reason or another have passed under State control. The late Dr. W. C. Rivers, a tuberculosis officer who knew the practitioner well from daily contact with him in an industrial area, has described him in "Through a Consulting Room Window" as sane and competent but disillusioned, the daily drudge of the panel system who in 30 or 40 years' time will give place to the salaried pensionable medical officer. At times, it is true, the general practitioner under the panel system would appear to have the worst of the bargain; but the horizon is changing and it is becoming evident that State schemes for social diseases lose half their value without him.

At the annual conference of the National Association for the Prevention of Tuberculosis, reported in another column, more than one speaker took this view. Dr. G. Lissant Cox remarked that the panel practitioner was not brought into the scheme of things nearly as much as he might be, owing to the unsatisfactory conditions under which he had to do his work. There was, he said, little time in panel routine for the long and careful examination of tuberculous patients, even if the practitioner was not handicapped by defective opportunities of training. Tuberculous patients were seen less and less frequently in the general hospitals; for the most part they went direct to a branch of the public medical service and were lost to the general teaching beds. Closer connexion was required, said Dr. Cox, between the tuberculosis dispensaries and the general hospitals if medical men were not to be sent out, as they were at present, knowing little of the signs and symptoms of early tuberculosis. Much depended on the good relations which ought to exist between the general practitioner and the tuberculosis service, and an important factor in this relationship was the quality of the work turned out by the tuberculosis officer. If the latter's administrative arrangements were so organised that his clinical work was of a low order, if he failed to undertake such specialised work as artificial pneumothorax treatment, it was futile to expect much interchange from him and his colleagues in general practice. Speaking as a practitioner, Dr. J. Cohen emphasised the same defects of the present system. When the patient leaves the sanatorium and returns to the care of the panel practitioner is the crucial moment of taking up his old life where he left off. In the scheme of divided responsibility, he said, it was easy for the practitioner to lose touch with the patient, and having lost touch to lose interest. The same story was being repeated in the case of venereal disease, antenatal work, child welfare, and juvenile rheumatism. Furthermore, the general practitioner as often as not knew little or nothing of what had happened to his patient during the stay in the sanatorium, and was therefore quite in the dark as to any special treatment which might have been applied. Pointing out that tuberculosis is being removed from the sphere of the medical student it followed that the practitioner might be unfamiliar with the present rapid advances in knowledge and technique and without the equipment to deal with tuberculosis when he finds it or when it is referred to him by the public authority.

To bring the tuberculosis officer and the general practitioner into closer touch presupposes mutual confidence. The tuberculosis officer must be a man of experience whom the practitioner can trust, and not just a migrant in the public health service. Unless he has the modern equipment of the tuberculosis specialist, the general practitioner is not likely to trust his skill. Public health committees have not yet come to realise that the treatment of tuberculosis is something more than the facile application of rest, fresh air, and good food; it involves the use of technical apparatus with a trained hand and mind. The practitioner also has much to give. There is knowledge yet to be gained on conjugal tuberculosis and marital infection, on pregnancy and tuberculosis, on relapses and recrudescences, on early signs and minor tuberculosis, on the causative factors in the acute, often fatal, forms of infantile tuberculosis, and the like, which can only be acquired in general practice. At the same conference Sir George Newman remarked that the Local Government Act of last year spells the end of the dual control of tuberculosis. Henceforth the public health committee which controls the tuberculosis service, called into being in 1912 as the result of the Astor Report, and the public assistance committee which now supersedes the guardians who controlled the advanced cases in workhouse, infirmary, and special ward and through out-relief, will meet under the roof of the same State authority. A new phase of the antituberculosis campaign is opening to which the practitioner has a contribution to make if he is allowed

MEDICAL MEDALS.

THE Brettauer Collection of coins and medals, which is a very famous one, and which is now in the possession of the University of Vienna, was made by Dr. Josef Brettauer of Trieste, who died 25 years ago. The circumstances in which it has since been housed, and why the cost of an illustrated catalogue has become a question of public appeal, will be found in a letter from the trustees for the upkeep of the collection which appears in another column (see p. 117).

The collecting of medals and coins is justified by the value of the tokens in confirming history, while affording an opportunity for the display of beautiful art. The coin and the medal have no exact differentiation, for the ancient coins, while representing money of a certain value, have had often, on the reverse, an illustration of some historical event. For example, there is a Byzantine coin whose reverse shows the Virgin Mary supporting the walls of Constantinople, a résumé of the history of that date which is very significant, while similarly a gold coin of Edward III. (a noble, worth about 8*s*. 6*d*.) commemorates on the back a victory over the French. It seems that the coin having a particular value in currency no longer "features" historic episodes, this rôle being left to the medal, which is struck to commemorate some event or person, and has no place in the currency. To this class belong the medals struck during the English Civil War, and the Christian token of Pope Gregory XIII. recording the festival or massacre of St. Bartholomew. The Brettauer Collection contains a complete group, in many subdivisions, of medals referring to the art and practice of medicine, and the field here is a large one. Those who have seen Mr. Forrer's catalogue of the collection of Greek coins belonging to the late Sir Hermann Weber, who began his fruitful labours through interest in medical medals, may recollect how fully medicine was represented. A rare drachma of Epidaurus, for example, has on one side the head of Apollo the father of Asklepios, and on the other Asklepios with his hand extended over his serpent, while beneath his throne is a dog. Mr. S. W. Grose, writing in THE LANCET with reference to the Weber catalogue, called attention to coins showing Epione, the wife of Asklepios, and the instrument known as the cupping vessel. The cupping vessel is on other Greek coins, especially those deriving from Thessaly, another centre of the worship of Asklepios. This town was the reputed home of Cheiron, the wisest of the Centaurs, and renowned for his skill in medicine. On the coins of Tricca, the legendary birthplace of Asklepios, appear an interesting type of Asklepios feeding his sacred serpent with a bird. Such are the prizes that arouse the antiquarian, but throughout the history of medicine great men, large events, and private generosity have been represented by numismatic art, and a graceful example of the last is furnished by the endowment at Corpus Christi College, Cambridge, by Dr. S. A. M. Copeman of an annual medal for medical research.

It is to be hoped that the trustees of the Brettauer Collection will obtain the practical help they need.

SENILITY AND HIGH BLOOD PRESSURE.

THE ætiology of high blood pressure, excluding cases which can be put down to chronic renal disease, remains obscure. The old belief that the blood pressure inevitably rises as age increases is a fallacy which dies hard. C. Laubry and R. Castéran [1] point out the importance of distinguishing between old age, a physiological condition, and senility, a pathological state, and recall the dictum of Vaqeuz that the vascular changes in the aged are due less to age than to the pathological conditions appertaining to age. They cite cases of men as old as 90, in whom the blood pressure was found to be well below the normal adult level. They have also observed that people exposed to hypertensive influences during their working years not uncommonly have a lowered blood pressure after retirement. This observation is readily understood if high blood pressure is regarded as a manifestation of cardiovascular hypertrophy in response to continuous or intermittent hypertensive influences. If the influence is removed before the vascular changes have gone beyond the stage of physiological hypertrophy, the blood pressure may fall again; but once this stage is passed a permanent rise is necessary to force the blood through the rigid and often narrowed arterial bed. It follows from this that in patients with high blood pressure and grossly degenerated blood vessels attempts to lower the pressure by violent means, such as purgation, are not merely illogical, but may cause a dangerous and even fatal

[1] Rev. de Méd., April, 1930, p. 251.

ischæmia of important tissues such as the myocardium and the brain. The physician, therefore, has no call to focus the attention either of himself, or still less, of his patient on the blood pressure reading. If there is much vascular, cardiac, or renal degeneration he should confine his treatment to the use of iodides, cardiac tonics, or diuretics, respectively. When the arterial degeneration is not excessive, however, no harm is likely to follow the use of purgatives, low-salt diet, or venesection, and such measures often relieve symptoms. Removal of the underlying cause is, of course, the ideal. That it is sometimes difficult to attain is illustrated by a case recently reported by F. Trémolières and P. Véran,[2] of a man of 28 who suffered from repeated attacks of herpes zoster, accompanied by severe headaches, vomiting, and amaurosis, and occasionally by clonic convulsions. During these attacks the systolic blood pressure rose as high as 280 mm. Hg, and the urine contained albumin. At the end of the attack the blood pressure fell to 130 mm. Hg and the albuminuria ceased. Later on the blood pressure became persistently high and death occurred, less than 12 months after the onset of symptoms, from failure of a hypertrophied heart and secondary degeneration of the kidneys. The association of herpes and hypertension in this case suggests that obscure nervous influences may play some part in causing paroxysmal and even permanent increase in the blood pressure.

DIFFERENTIAL BLOOD CULTURE IN SINUS THROMBOSIS.

AN ingenious method of blood culture, introduced by Reuben Ottenberg,[3] seems likely to yield useful information in certain cases of mastoid disease and sinus thrombosis. Quantitative blood cultures are made simultaneously from the two internal jugular veins and from one of the limb veins. In cases of lateral sinus thrombosis differences in the degree of bacteræmia may be detected in the blood in the two internal jugulars, and this may give information of clinical importance. The simple presence in either of the jugulars of a bacteræmia much greater than that found in the limb blood points to an intracranial venous infection, and a quantitative difference between the two sides points to unilateral sinus thrombosis. The side of the infection is not indicated, however, by the result of the blood culture, since upon blockage of the sinus the blood flow is reversed by inflow from the smaller collateral channels, while blood from the region of the thrombus may also reach the opposite jugular by more circuitous routes. The passage of organisms into one or other jugular is also determined by their distribution in the thrombus. Either they may be escaping into the blood stream in large numbers from one or other end of an infected thrombus or they may be more or less completely immured in comparatively uninfected propagated clot. But although these somewhat numerous complexities prevent a differential culture from determining the side of the infected sinus, a difference in the bacteræmia indicates with some certainty the presence of such an infection, and its exact locality is usually indicated by other signs. The question arises, in what proportion of cases of thrombosis is such a positive result obtained? Ottenberg obtained a definite positive indication in 10 out of 20 cases of proved sinus thrombosis or phlebitis,[4] and in the same series of cases of proved thrombosis the results were negative five times. A negative culture, therefore, does not exclude its presence.

The method has a further sphere of usefulness in cases where mastoid disease is complicated by osteomyelitis, pneumonia, or endocarditis, and it is especially difficult to diagnose an associated sinus thrombosis. Here an excess of bacteria in the jugular blood over that found in the systemic blood gives valuable information in pointing to the latter, and, conversely, where the results are essentially the same the likelihood of the sinus being at fault is reduced. The work reported is extremely interesting and may prove of value in diagnosis, but as Ottenberg clearly recognises, there are certain limitations and possible sources of fallacy. For example, the speed of elimination of organisms from the blood stream and variation and irregularity in their rate of transfer to it must be considered; and also the important question of post-operative bacteræmia. It is recognised that after operation bacteria can pass into the blood from septic areas and appear in cultures made from the related veins without any interruption of convalescence. Ottenberg suggests that the principle upon which his report is based may be extended to other regions of the body.

HERPES ZOSTER AND ENCEPHALITIS.

THE association of zoster with encephalitis is rare. In a recent paper Netter [5] described 16 cases, details of which he had been able to collect, and from a consideration of this material he concluded that these were examples of encephalitic lethargica in which zoster was a complication. It is, of course, well known that injury to the first sensory neurone predisposes to invasion of this neurone by the zoster virus—the so-called symptomatic zosters—and it is possible that Netter is right in thinking that the virus of lethargic encephalitis may occasionally prepare the way for a zoster infection. But an examination of the published details of Netter's cases makes one doubt whether he is entitled to place this interpretation on all of them. In one patient there was an interval of six years between the onset of encephalitis and the appearance of zoster, and in two others, one of which was observed by C. I. Schiff and W. Russell Brain, the zoster eruption actually preceded the encephalitis. Schiff and Brain report their case on p. 70 of our present issue, and at the same time they review the literature. In their opinion, cases of encephalomyelitis with zoster fall into three groups. One group consists of those in which the occurrence of the two conditions is a mere coincidence, a second group comprises cases of encephalomyelitis complicated by a symptomatic zoster, whilst the third and most interesting constitutes a true zoster encephalomyelitis. It is in this last group that Schiff and Brain would place their own case. Encephalomyelitis is recognised as a complication of many diseases due to filtrable viruses, and there seems no reason for doubting that the same holds good for zoster infections also. There is a considerable body of evidence, both clinical and scientific, pointing to the identity of the viruses of chicken-pox and zoster, the latter being a neurotropic variation of the former. Zoster is a posterior poliomyelitis and it is easy to understand how the virus

could spread to adjacent portions of the central nervous system with the production of a meningo-encephalomyelitis, the type of which would be determined by the distribution of the zoster infection. A meningeal reaction has long been recognised as a constant feature of zoster and occasionally the signs and symptoms of meningitis are present. In support of their conception of a zoster encephalitis Schiff and Brain point out that in the cases which they would put in this category, meningeal symptoms are a prominent feature and often show a local predominance corresponding to the distribution of the zoster. The demonstration of the virus of zoster in the cerebro-spinal fluid of their case lends support to this view.

ABOUT DELIRIUM TREMENS.

AT a meeting of the Society for the Study of Inebriety, held at the rooms of the Medical Society of London on Tuesday last, Dr. E. F. Wills, resident medical superintendent at Rendlesham Hall, described his personal experiences with sufferers from delirium tremens. The main question with which he dealt, as a clue to treatment, was whether the sudden withdrawal of alcohol is a factor in the onset of the delirium. Fairly admitting that this sequence of events has been flatly denied by certain authorities, he detailed instances, which had come under his own observation, showing that delirium is more likely to manifest itself when alcohol has been abruptly discontinued. He further explained the occurrence of delirium tremens in association with shock or surgical interference as an example of the same phenomenon, believing that when such cases are closely investigated the real factor determining the symptom will be found to be the withholding of alcohol up to at least the amount which the patient had been previously imbibing. Therefore he holds the immediate bar to all alcohol to constitute incorrect treatment, advising that, together with the appropriate narcotics and purges, alcohol in "tapering" doses should be exhibited.

Dr. Wills's paper concluded with the comforting statement that the number of cases of delirium tremens is on the decline in this country in response to the raised price of alcohol and the shorter hours during which its public purchase is sanctioned by law. This was a simple and practical communication.

MUCOUS MEMBRANE IN THE SKIAGRAM.

RADIOGRAPHY of the stomach and duodenum is passing into a second stage of its development. In the first stage the stomach was filled with the opaque meal and the state of the lumen was thus made apparent. In the second stage, for which we are indebted to the pioneer work mainly of Akerlund, Forsell, Holzknecht, Schwarz, and Berg, interest may be said to have been transferred from the lumen to the wall itself, the investigation being directed to the contour of the mucous membrane. While the former method is of value in determining size, shape, tonus, and peristalsis, the latter is a considerable refinement where organic disease is concerned. A. Rohrbach[1] gives a full account of the technique he uses which closely resembles that recently described in our columns[2] by V. J. Kinsella, and attributed by him to J. O'Sullivan. Only half a tablespoonful of the barium meal is given and it is important that this should be of maximal surface-tension and free from particles. This small amount is observed on the screen and by suitable manual compression it is made to fill the furrows of mucous membrane, leaving the intervening ridges bare. Films are taken with Berg's well-known apparatus. Normally the mucous folds should appear as parallel lines of uniform width; a radial arrangement indicates the present of an ulcer at the point of convergence. The main advantages of this over the earlier method are that by varying the degree of compression the presence of multiple ulcers can be determined, that ulcers can be seen on the anterior and posterior surfaces when their craters do not project in profile from the lesser curvature, and that information is given regarding the degree of inflammatory thickening of the mucous membrane surrounding the crater. The method is also of service in the investigation of carcinoma. Atrophy of the mucosa, as in pernicious anæmia, and the inflammatory changes of gastritis are also well brought out.

A HOSPITAL SWEEPSTAKE.

THE particulars of the first sweepstake to be organised in aid of the Dublin hospitals were published last week. Six hospitals are to share the profits—namely, Jervis-street, Sir Patrick Dun's, National Dental, National Maternity, Children's (Harcourt-street), and St. Ultan's. A sum of £25,000 is guaranteed for distribution in prizes, but the promoters hope that, as the result of the sale of tickets, they may have an amount at their disposal of at least four times that sum. Of the total receipts, 80 per cent. will be distributed in prizes, the other 20 per cent. covering the expenses as well as the profits for distribution to the charities. The sweepstake will be on the November Handicap, and the draw will take place on Nov. 17th, in the Mansion House, Dublin. It is clear that, unless the sale of tickets goes beyond expectation, the promoters must be content with a comparatively small sum for the benefit of the charities.

CONSTITUTION OF HUMAN MILK.

EXACT information about the constituents of human milk at all periods of lactation is important for the preparation of artificial foods for infants. Much attention has been paid to its composition during the first month, but after that there has been a gap. We therefore welcome new observations, just published by workers at the Royal Free Hospital[1] and elsewhere, on the milk of 51 women attending welfare centres. It appears that the calcium content is lowest for the first two weeks of lactation, rising gradually to a maximum during the first four months; it maintains a fair level after the fourth month, but slowly decreases. The rise in the proportion of calcium coincides with the time when the baby is increasing its intake of milk by the largest daily amount, while the subsequent decrease will be balanced by the supplementary foods that the child will take about the age of six months. The proportion of phosphorus runs parallel with calcium up to the end of the fourth month, but then remains almost constant. This, it is suggested, may be because growing soft tissues need more phosphorus than calcium. The ratio between the two elements is of great importance in the ætiology of rickets, and this study indicates that during the first six months of life a ratio of CaO to

[1] Widdows, S. T., Lowenfeld, M. F., Bond, M., and Taylor, E. I.: Biochem. Jour., 1930, xxiv., 327.

P_2O_5 per 100 c.cm. of milk greater than 1, and approximately 1·3, is probably most suitable for the child, provided the vitamin factors are adequate. Sugar is at its lowest value in early milk, but by the end of the first month the proportion has risen to an average which remains at about 7 per cent. of lactose throughout lactation. The low values for sugar in early milk are interesting when we consider the very general use of highly sweetened food in the artificial feeding of young infants. The highest percentage of protein proved to be in the first three days after parturition; the level then fell steeply during the first week to reach an approximate average of 1·4 per cent. at the end of the thirteenth day. A gradual decrease takes place to just under 1 per cent. during the last month of lactation, but this is counterbalanced by the larger volume of milk consumed. Most authorities give 1·5 to 1·6 as the usual figure for protein, but perhaps the percentage varies a good deal. In cases where there was a pathological condition of the breast the percentage of sugar in the milk was found to be low.

GROUND ITCH OR WATER SORE.

WHAT is ground itch? Most practitioners in the tropics would probably answer that it is a dermatitis of the feet attacking barefoot coolies who paddle about in mud infected with ankylostoma, and is caused by the larvæ boring through the skin and irritating it. The term has, however, become a popular designation for all kinds of dermatitis of the feet, and therefore misleading. For example, in Florida 320 people complaining of ground itch had only one case of ankylostoma infection among them, but 30 kinds of skin disease. Hence Prof. F. Fülleborn of Hamburg had reason for feeling that the published accounts of the disease ground itch require critical discussion. The disease, he says,[1] was first described by W. E. Lloyd Elliott in 1900 as *pani-ghao* (water sore), characterised by itching blisters of the feet, especially between the toes and affecting barefoot labourers in the Assam tea gardens. It has since been reported from Bengal, China, Queensland, the West Indies, and elsewhere, always in people who wade or paddle in mud more or less contaminated with human fæces, and frequent in proportion to the extent of this contamination. Ankylostoma infection and ground itch are often reported together, by coincidence. Ground itch is not heard of in dry Egypt, nor is it reported from the porous volcanic soil of Guatemala or Sumatra where ankylostoma is very prevalent. It has indeed been set up by applying ankylostoma larvæ in mud to the forearm, but only if the mud contained human fæces. It is probably of microbial origin—it is cured by salicylic acid—though its cause is as yet unidentified. Fülleborn, after careful examination, expresses a hope that the term ground itch will no longer be employed in medical literature, and that henceforth the disease should always receive the name suggested by its discoverer—namely, pani-ghao or water sore.

OVER £8200 has been received towards the proposed memorial to Sir Patrick Manson (see THE LANCET, 1930, i., 142). Further donations will be gratefully acknowledged by the President of the Royal Society of Tropical Medicine and Hygiene, 11, Chandos-street, London, W.1.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. T. Creaser to be Surg. Capt.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt.-Comdr. (D). W. H. Hume to *Victory*, for R.N Hospital, Haslar; Surg.-Lt. R. Erskine-Gray, to *Pembroke*; Proby. Surg. Sub.-Lt. G. S. Thoms to *Victory*, for R.N. Hospital, Haslar.

ROYAL ARMY MEDICAL CORPS.

Twenty-five permanent commissions in the Royal Army Medical Corps are being offered to qualified practitioners, under 28 years of age, registered under the Medical Acts. There will be no entrance examination, but candidates will be required to present themselves in London for interview and medical examination. At the same time, a certain number of temporary commissions under similar conditions as regards age and qualifications will also be offered. Applications should reach the War Office not later than July 20th. All information as to conditions of service and emoluments may be obtained from the Under Secretary of State, The War Office (A.M.D.1), Whitehall, London, S.W.1.

Lt.-Cols. N. D. Walker and G. A. K. H. Reed retire on retd. pay.

The undermentioned Majs. (temp. Lt.-Cols.) to be Lt.-Cols.: T. C. C. Leslie, vice Lt.-Col. S. M. W. Meadows, promoted, L. G. Gibson, vice Lt.-Col. N. D. Walker, and T. T. H. Robinson, vice Lt.-Col. G. A. K. H. Reed, to retd pay.

The undermentioned Majs. to be Temp. Lt.-Cols.: A. C. Amy, W. Mitchell, and E. Gibbon.

Lt. T. F. M. Woods to be Capt.

ARMY RESERVE OF OFFICERS.

W. D. Speedy to be Lt.

TERRITORIAL ARMY.

Capt. L. M. Weeks to be Maj.

Supernumerary for Service with O.T.C.—Capt. A. Fowler to be Maj.

Lt. J. F. Fraser to be Capt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Maj. G. B. Gill, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Capt. B. Stewart, from Active List, to be Capt.

ROYAL AIR FORCE.

Group Capt. H. V. Wells to be Air Commodore.

Wing-Comdr. H. W. Scott to be Group Capt.

Squadron Leaders R. S. Overton and D'Arcy Power to be Wing Comdrs.

Flight.-Lt. W. S. Stalker to be Hon.-Squadron Leader.

RESERVE OF AIR FORCE OFFICERS.

Flight.-Lt. T. L. P. Harries relinquishes his commission on completion of service.

INDIAN MEDICAL SERVICE.

Lt. K. Rai to be Capt.

Lt.-Col. J. W. McCoy retires.

GOOD SERVICE AWARD.

The Secretary of State for India has approved the grant of a Good Service Award to Maj.-Gen. Sir C. C. Manifold, K.C.B., C.M.G., I.M.S. (retd.).

COLONIAL MEDICAL SERVICES.

The following appointments have been made: Maj.-Gen. H. P. Barrow, Health Officer, Leeward Islands; Miss A. E. Connan, Lady Medical Officer, Straits Settlements; and Dr. W. P. Jones, Medical Officer, Malaya Medical Service, Straits Settlements.

THE death occurred in London, on July 5th, of Dr. Gavin Brown Clark, sometime Member of Parliament for Caithness and Sutherland. Dr. Clark, who was in his 84th year, qualified at Edinburgh in 1874 and was for many years resident physician to the Dunblane Hydropathic Establishment.

ST. BARTHOLOMEW'S HOSPITAL SURGICAL WING.—On Friday last the Lord Mayor of London formally opened the new surgical wing. A service of dedication was conducted in the Paget ward by the Bishop of Chester (Dr. H. L. Paget), a son of the late Sir James Paget, surgeon to the hospital. An illustrated description of the wing and its equipment was published in our last issue.

CLINICAL INTERPRETATION OF AIDS TO DIAGNOSIS

(A Series of Special Articles Contributed by Invitation.)

LXXX.—INTERPRETATION OF DENTAL RADIOGRAMS.

(WITH ILLUSTRATIVE PLATE.)

PART III.*—Apical Infection.

As has already been stated, this does not reveal itself in a radiogram until the products of its putrefaction of the pulp have changed the normal picture of the surrounding tissues. (The electric test for pulp vitality and stereoscopic radiograms are of value here in differentiating the affected teeth.) When apical infection of the chronic type has taken place, the apex of the root is seen to be surmounted by a rarefied area, there being a breach at this point in the lamina dura. The area of bone destroyed varies in size from a small crescentic cap (Fig. XIV.) to a cavity the size of a filbert nut, apparently involving adjacent teeth. The outline of the radiolucent area is of importance. Where it is clearly defined, even and hard, the contents in the bony space are usually a pus sac which often comes away attached to the root during extraction (Fig. XV., A). When the outline is indefinite, irregular, and soft, no true demarcation from rarefied area to normal bone can be seen. The one merges into the other. This space will be found to contain a mixture of pus and granulation tissue, or solely granulation tissue, constituting the "apical granuloma" (Fig. XV., B). The importance lies in the fact that although the former appears in a radiogram as a blacker and more obvious area, it is probably less harmful. It is seen when resistance against the septic invasion is good, and is often surrounded by an area of sclerotic bone. The granuloma appears to be present in cases when the infection is gaining ground. Since it is more friable than the fibrous capsule of the pus sac, the granuloma does not readily come away with the root, and it tends to persist as a focus of infection, even after the removal of the tooth.

Unlike the circular smooth-lined cavity of the chronic abscess, the cavity of the granuloma is mostly loculated. Undoubtedly the open operation which consists in removing the tooth and deliberately enucleating the granuloma is to be preferred to ordinary extraction.

A number of these operations reveal a certain inadequacy of the radiogram to show the full extent of a granuloma, for it is sometimes found that under the shelter of a rather dense alveolar plate rarefaction apparently confined to the apex of one tooth has spread through the cancellous tissue of the interdental bone and involved adjacent teeth.

Patients who develop the circumscribed type of apical rarefaction are mostly young, and the septic area may be harboured for years without apparent damage to other organs; whereas the granuloma occurs later in life and is associated with poorer resistance and secondary symptoms.

A set of dental radiograms of an adult patient in whom a number of teeth have been devitalised may easily show both black abscess areas and greyish granulomata side by side.

A patient of 60 years with a tooth showing a chronic abscess enjoyed good health for many years, annual radiograms showing the area to be of constant size and demarcation. (Fig. XVI., A and B). A final radiogram showed the septic area to have broken bounds, the outline of the cavity becoming blurred and extending on one side (Fig. XVI., C). This was followed shortly by cardiac disturbance of toxic origin, which has not recurred since the tooth was removed.

Sclerosing Osteitis.

Emphasis has been given to the phenomenon of sclerosis in these infections because of its diagnostic and prognostic importance.

It is seen, affecting the bone more or less uniformly, as an accompaniment to the generalised exostosis of the roots in those cases of low-grade infection where resistance is good (Fig. XIII.). Localised, it is seen first as a thickening of the lamina dura (Fig. XVII., A), and later as a fleecy patch around a mildly septic tooth or surrounding an area of apical rarefaction, and it may be deposited in response to constant trauma to buttress the root of the tooth which is subjected to undue strain, such as one supporting a bridge. It is present in the interdental tissue as a natural barrier to further rarefaction (Fig. XVII., B) and its formation is stimulated by suitable treatment.

* Parts I. and II. appeared in THE LANCET last week.

DESCRIPTIONS OF ILLUSTRATIONS ON SPECIAL PLATE.

PART III.

FIG. XIV.—Apical infection. Crescentic area of rarefaction bulging into the floor of the antrum, showing the ease with which that sinus may become infected from a septic tooth.

FIG. XV.—(A) Apical infection. Clear definition of the dark area (H) suggests an abscess sac containing pus.
(B) Area H' at apex of crowned premolar undefined and fading gradually into normal bone indicates a granuloma.

FIG. XVI. (A, B, and C).—Showing chronic abscess G, clearly defined in 1926 (XVI., A). In 1927 it was rather larger but still well defined within a smooth white wall (XVI., B). In 1928 the abscess has spread to the neighbouring tooth and has a hazy irregular wall (XVI., C).

FIG. XVII.—(A) Sclerosis of lamina dura (F).
(B) Sclerosis (O) in the interdental tissue.

FIG. XVIII.—Sclerosing osteitis (D) occurring as a zone round a dead molar. Note areas of apical rarefaction (E), and some absorption of one root (C).

FIG. XIX.—Sclerosis changing to rarefaction. The areas between the teeth are progressively more radiolucent from left to right of the film.

FIG. XX.—(A) Rarefying osteitis accompanied by "streaking" (A), commonly seen in the lower incisor region.
(B) Rarefying osteitis (B) shown as a radiolucent (dark) area with hazy outline.

FIG. XXI.—Typical specimen of the dental film of one of the cases of residual dental sepsis quoted. Observe the insignificant appearance of the residual root (Z).

FIG. XXIII.—Persistent socket (Y) due to sclerosis in the surrounding bone and infection in the socket.

FIG. XXIV.—Enlarged film of alveolar ridge showing residual infection producing a condition of non-healing rugged edges with constant shrinkage of the ridges and soreness under the plate due to spiculation.

FIG. XXV.—(A) Early dental cyst—almost spherical—surrounded by normal appearing bone from which it is separated by a thin though clearly marked layer of compact bone.
(B) Two small dental cysts in the edentulous mandible like the one in the previous figure (XXV., A). Simple extraction does not suffice. The cyst must be removed by open operation, otherwise it will continue to grow.
(C) A larger cyst of the mandible beginning to lose its spherical form and to spread in the direction of least resistance.

FIG. XXVI.—Very large dentigerous cyst formed around an impacted third molar and extending from near the root of the canine tooth in front rising in the ascending ramus almost to the notch.

FIG. XXVII.—Subacute osteomyelitis of the mandible. Note sequestra embedded in granulation tissue (X) and surrounded by a dense area of sclerosis in the bone. Sequela to the removal of teeth for periodontal disease. (A) Vertical film; (B) horizontal film showing swelling on buccal aspect of the jaw.

The presence, therefore, of a condensing osteitis in moderation is a good sign, for it demonstrates that at the time when the radiograms were taken the system generally was reacting favourably against the invasion, and these cases are often suitable for conservative treatment. At times sclerosis takes place to an extreme degree, and localised patches of uniformly radiopaque bone are seen extending some distance from an affected tooth into the medulla of the jaw beyond (Fig. XVIII.). In other cases the local and general resistances become impaired and rarefaction supervenes upon the sclerosis (Fig. XIX.). Devascularisation of the area, which accompanies the sclerosis type of reaction, is a disadvantage from both a pathological and a surgical point of view. The greater the condensation the more removed is the nidus from the phagocytic elements of the soft tissues. Cases are on record where metastatic lesions have persisted long after extraction of the teeth, only to be cleared up when the sclerosed bone itself was removed.

From a surgical aspect, excessive sclerosis, which is usually accompanied by hypercalcification and increased brittleness of the teeth, not merely offers mechanical difficulty to the removal of the teeth but, where ordinary extraction is the procedure, the necessary trauma and consequent "bacterial shower" are greater. Also, owing to the impaired blood-supply, the socket heals with difficulty, is easily infected, and is a familiar dental sequela to the operation of extraction known as "dry socket."

If the cancellous tissue be examined critically at some little distance from the source of infection, small dark (radiolucent) spots are frequently seen, each surrounded by a ring of sclerosed bone. These areas cannot be adequately reproduced in a print of a radiogram but are clearly visible on a viewing box. It has been suggested [1] that these areas represent colonies of living bacteria, and evidence of their infectivity is deduced from the facts that (*a*) they are found in clusters around infected teeth; (*b*) they occur in the interdental septa where marginal rarefaction is taking place; (*c*) they may be seen also in the bone from which teeth known to be septic have been removed months previously. Their appearance in the edentulous bone invariably means residual sepsis which can be shown bacteriologically.

Heath [2] has found that when they are present interference with the tooth (e.g., extraction) has consistently been followed by a fairly acute systemic reaction with an increase of the secondary symptoms. The fate of these small dark spots depends on the patient's resistance. (1) They may heal—producing the little sclerotic spots which provide evidence of past infection overcome. (2) They may remain in statu quo ready to break out when the body's resistance is lowered by some other agent—e.g., overwork, old age, intercurrent disease. In this way residual dental infection may persist for years after the removal of all the teeth, and may produce secondary symptoms, such as arthritis. (3) Resistance being poor, these dark spots may spread and coalesce, giving rise to the condition of caries in the bone—one form of the rarefying osteitis dealt with below (Fig. XX., B).

Rarefying Osteitis.

When the conditions of bacterial virulence and bodily resistance are unfavourable, a rarefying osteitis is observed. This condition may be seen on the margin of the destructive lesion, or deep in the medullary tissue. It is characterised by a removal of the lime-salts, with accompanying lack of brilliance in the radiographic shadow of the osseous network, so that the area has the appearance in the negative of having been painted with a reducing agent (Fig. XX., A). When an area like this is not surrounded by sclerosed bone, it fades away gradually into the normal tissue. The condition is often seen between and below the apices of lower incisor teeth as hazy radiolucent streaks (Fig. XX., B), seemingly indicative of the drainage of septic material from around these teeth into the body of the jaw. The same condition may be observed in the maxilla in the incisor and premolar regions extending around and beyond the roots of infected teeth, but here it is more diffuse and less easy to detect (Fig. XX., B). It may be rendered more obvious, however, by increasing the illumination and regarding the films at some distance, and it is usually well brought out in positives carefully made upon printing-out paper, but not when bromide paper is used. In the dried specimen it may be seen as a zone of osteoporosis surrounding the cavity of a granuloma.

This phenomenon signifies the unobstructed diffusion of sepsis through the cancellous tissue, and demonstrates the gradual dissolution of large areas of bone. It is seen in more recent infections, and is found in patients, often young, suffering from rapid periodontal disease accompanied by loosening of the teeth and extreme debility. When the teeth are extracted, the bone, which is being replaced by inflammatory granulation tissue, feels soft and mashy. Cases revealing this condition have little resistance to the infection, and are usually ill as the result of it, and therefore careful radical treatment is indicated.

Residual Infection.

Except in the young and vigorous it is difficult to say with what efficacy infection, once it has gained access to a jaw, is ever removed. Bacteriological examination of the apices of extracted adult teeth are rarely sterile. Where there is one septic tooth in a jaw contamination of the roots of other teeth appears to ensue. In those few cases of this type where it has been feasible to extract a second tooth clinically and radiographically sound—in one case, in fact, on the opposite side of the jaw—and under conditions calculated to avoid extraneous contamination, the same organism has been grown from the root of the sound tooth as from the septic one. The conclusion to be drawn from this is that the bone of the jaws does not easily recover from dental sepsis; the longer septic teeth remain in the jaw the less chance the patient has of complete recovery from infection after their removal. Two cases recently came under my observation, both rheumatic—one with the knees so badly affected that walking was almost impossible, and the other with fixation of the right elbow. Both patients exhibited radiological evidence of residual dental sepsis, while a complete medical overhaul revealed no other obvious source of toxæmia. Streptococci in pure culture were obtained from the medullary portion of the jaws of both patients, and following treatment of the dental sepsis the affected joints recovered (Figs. XXI. and XXII.).

It is not uncommon to see patients still suffering from focal dental toxæmia when the jaws have been edentulous for ten or more years. Where tooth fragments are left behind the chances of complete disappearance of infection are still further reduced, and the practice of ignoring these pieces is culpable. Jaws edentulous so far as external appearances are

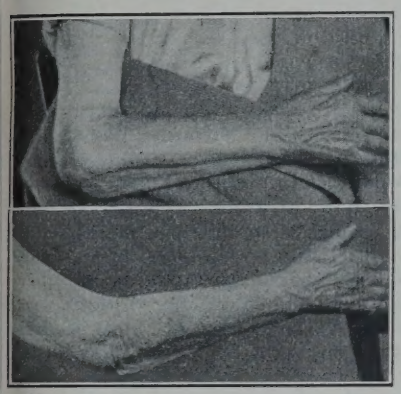
[1] Colyer, S.: THE LANCET, 1922, i., 175.

[2] Heath, J. S. R.: The Correlation of the Radiographic Bone Pathology of the Jaws with the Incidence of Secondary Infections, Dental Cosmos, September, 1923.

concerned denote nothing. There may be buried roots, misplaced teeth, or areas of rarefaction invisible to clinical inspection. In every case of focal sepsis a full set of dental films should be taken and there is much to be said for the growing practice of checking the success of dental operations by further radiographs after a selected lapse of time.

Radiographically, residual sepsis is shown as a persistent area of apical rarefaction or as a patent (i.e., non-ossifying) tooth socket persisting after the gum has healed over it, and constituting a type of granuloma, or as a diffuse area represented by small dark spots and streaks (Fig. XXIII.). It appears also in cases of periodontal disease where recuperation has been poor, or sometimes as an area of diffused rarefaction localised in the alveolar margin, or as a general and progressive shrinkage of the alveolar ridges, especially in the mandible, which (when the film is examined closely with a lens) may present a saw-like edge due to spiculation (Fig. XXIV.). Clinically, the symptoms of this are progressive loosening of artificial dentures—some patients requiring a new denture each year—and a chronic soreness under the plates due to the pressure of mastication trapping the mucosa over the roughened surface of the bone. Buried teeth and impacted lower third molars and other misplaced teeth appear to become infected sooner or later, and it is wiser that they should be removed early whilst the bones are soft and vascular than that they should be left till the sclerosis of the bone and brittleness of the tooth complicate the operation or until gross rarefaction imperils the recovery from infection. A devitalised tooth with the root canals efficiently filled and no pathological signs in the bone may not be a harmful tooth, but it is at least a suspicious one, and both it and the patient's health picture should be watched accordingly. A far greater responsibility is undertaken in advising its retention than its extraction.

FIG. XXII.



Edentulous patient, aged 68, who had complained of pain, swelling, and immobility of the elbow-joint for two years. Removal of some buried root fragments for cultural examination produced but slight relief. After eight weeks' pause the residual infection was treated by intra-oral diathermy and weekly doses of autogenous streptococcal vaccine. After ten weeks' treatment the pain had ceased and the range of movement greatly increased. Since this time (two years ago) the recovery has been maintained, and the patient has full use of her right hand, previously functionless.

Dental Cysts.

The radiographic appearances of dental and dentigerous cysts are somewhat similar. The difference lies in the fact that a dental cyst is found in relation to the root of an infected tooth or one with a past history of trauma, and may persist in the jaw years after extraction of such a tooth; whereas a dentigerous cyst is found in connexion with a vital unerupted tooth, whether normal or supernumerary, which it may enclose partially or entirely.

In a negative a dental cyst appears as a very clearly defined radiolucent area involving the apices of one or more teeth (Fig. XXV., A, B, and C). The bone cavity, which this radiolucent area depicts, is seen to be surrounded by a solid, cortical light line, and the bone beyond is of healthy appearance. The outline is clearly defined and regular. In its earlier stages a cyst is more or less globular, but with growth it tends to bulge in the direction of least resistance.

DENTIGEROUS CYST.

Cysts of this nature develop around the crown of an impacted normal (Fig. XXVI.) or supernumerary tooth. In examining the radiograms of developing teeth, the crowns of the forming teeth are seen to be enclosed in a capsule of bone. A dentigerous cyst is formed by the proliferation of the epithelium lining this chamber and its consequent distension by the fluid of degeneration. Mostly the fibrous tissue sac which encloses the epithelium is attached firmly to the neck of the tooth, with the result that radiograms show the crown only projecting into the radiolucent area. In later stages, however, extension toward and around the apex of the root may be such as to enclose the tooth entirely.

Other types of odontoma are less frequently observed.

Diffuse Osteomyelitis and Necrosis.

Fortunately, owing no doubt to the good blood-supply, infections from the teeth nearly always remain localised. When, however, the relative conditions of infection and local resistance permit it, spreading takes place along the marrow spaces of the bone. A large area is involved and a condition of osteomyelitis results. In the acute form the clinical evidence is conclusive. In the subacute and chronic types, radiographic examination is useful to watch the progress.

In the earlier stage there is a generalised rarefaction over the area and the cancellous spaces appear enlarged. Later, channels are formed which extend along the bone and give a worm-eaten appearance. Pieces of bone which are cut off from nutrition become necrosed and in advanced cases sequestra are formed. These can be seen as islands of bone entirely surrounded by a dull (radiolucent) "shadow." During healing new sequestra are frequently formed, causing more or less disturbance and discomfort, and should be removed after location by fresh radiograms. Subacute cases (Figs. XXVII., A and B) may persist for months without causing the patient more than soreness, and in neglected cases the bone may become weakened to the point of fragility. In one case recorded, spontaneous fracture of the mandible in the molar region occurred before the patient presented himself for treatment. The jaw was fractured at night while he was lying on the affected side of the face.

Impacted Teeth and Foreign Bodies.

Only a small percentage of unerupted and impacted teeth develop cysts of the follicle. Their importance, however, lies in the amazing variety of complaints, other than dental, to which they give rise. Current dental literature is full of examples where removal of the impacted tooth has led to immediate and complete cessation of symptoms. When the teeth were healthy the secondary symptoms were mostly of the reflex nervous character. Undoubtedly some cases of neuralgia, such as one excited by impaction of the upper third molar against the tooth in front of it, are due to resorption of the dentine of the latter and irritation of its pulp, but often it is the impacted tooth

itself which causes the trouble. The teeth most frequently misplaced are the third molars, the canines, and the second premolars, upper and lower.

Lastly, the possibility of the presence of supernumerary denticles and of foreign bodies should not be overlooked. Usually there is a history of accident such as a broken hypodermic needle. Occasionally, however, during the extraction of several teeth, a metal filling or a fragment of enamel may be dislodged from a tooth and escape into its own open socket or an adjacent one, where it may remain. This foreign body, if overlooked, may cause only local or even no discomfort afterwards, but perhaps years after the accident secondary symptoms may occur.

I have to thank Dr. W. H. Coldwell for the negatives from which Figs. XXV., C and XXVI. were made. Fig. III., C is taken from an article on "Nasmyth's Membrane and Periodontoclasia" by Kurt H. Thoma.† Also I have to thank Mr. Owers, of the Kodak Company, for help in preparing the illustrations for reproduction.

MEDICINE AND THE LAW.

Irregularities at Inquests.

THOSE who do not wish to see the coroner's inquest abolished must anxiously watch judicial criticisms of its procedure. Bench and bar regard the inquest with less reverence than is felt by laymen. They look upon it as a clumsy archaism and to some extent an unnecessary duplication of criminal procedure. Members of the bench notice the informalities and the divergences of local usage due to the strong personal authority of the coroner. Members of the bar know the tribunal as one where there is no right to address the jury and where even the examination of witnesses is a concession. Two recent cases in the King's Bench Division have revealed irregularities sufficiently grave to lead to the quashing of the inquisition. In both cases the judges have repeated with emphasis the dictum, to which Lord Reading and Lord Hewart have given currency, that it is not enough that justice should be done; it is not less important that justice should seem to be done. In other words, the outward forms of judicial procedure are not to be ignored. In particular, if a jury is summoned and is called upon to declare its verdict, the verdict must be based upon the evidence given in open court with no other assistance than the summing-up of the coroner himself.

AN INQUISITION QUASHED.

On June 17th the Divisional Court quashed an inquisition taken before the coroner for Hertfordshire at North Mimms upon a death caused by a traffic collision. The ground on which the court interfered was that the coroner's officer, who was also a witness, was present with the jury during their retirement. The court accepted his statement that he did not speak to anyone in the jury room, and also the coroner's statement that he was unaware that his officer was with the jury. But the judges regarded the irregularity as fatal. The coroner's officer, an official whose existence is nowhere recognised by statute but whose services are frequently conspicuous at the inquest, evidently requires careful watching. Other irregularities, in part arising from looseness of procedure in respect of jurymen when not in open court, vitiated an inquest at Kingston-upon-Hull earlier in the present year in circumstances reported in THE LANCET of Feb. 22nd (p. 426). Two men had been killed in a traffic accident and the inquest resulted in a verdict of manslaughter against a motorist. The first of a series of alleged irregularities was that the coroner had viewed and discussed a damaged vehicle before the inquest in company with a man who afterwards acted as foreman of the jury. The Divisional Court accepted without reserve the coroner's statement that at this viewing of the vehicle no discussion of the causes of the accident took place. There was, said Mr. Justice Talbot, ample opportunity for discussion and, even though an inquest might be an inquiry less formal or rigid than a criminal trial, it was contrary to public policy that a coroner should take, before an inquest was held, one or more persons who were to serve on the jury, and privately investigate with them any of the facts of the case with or without discussion. The judges thought that what had happened would have amounted to misconduct on the part of the coroner even at common law and that they would have been justified on that account in quashing the inquisition. The judges, however, had powers in addition to their powers at common law. They could take action under Section 6 of the Coroners Act of 1887, if it were "necessary or desirable in the interests of justice." The judges considered that nothing should be allowed which made it certain that the jury would be influenced by things which they had seen or heard outside the court; it was clear that the coroner's visit to the garage with the man who became the foreman of his jury must have had this effect. Earlier in the judgment Mr. Justice Talbot had criticised the practice at Hull of summoning a coroner's jury from a total panel of only 16 or 17 persons. The court felt bound to say that to confine the area of selection to so small a number in so large a town seemed very objectionable. The principle of the jury system was the determination of questions of fact by persons taken at haphazard from the body of qualified persons. To have a small panel of "regular jurymen" was an entire departure from that principle, and the practice had brought about the irregularity already described. In spite of the Divisional Court's opinion, it would seem that the judges were here on no very sure ground. Although it is common to use the voters' list as a list of jurors, Parliament has deliberately preserved (in Section 52 of the Juries Act of 1825, read with the saving clause in Section 45 (5) of the Coroners Act of 1887) certain ancient and rather vague usages in respect of coroners' juries. The coroner seems to have a free hand provided that he obtains the attendance of the statutory number of qualified jurymen. When the great Lord Mansfield was laying the foundations of the commercial law, it is said that he liked to employ the same little band of experienced merchants as his special jurymen at the Guildhall to determine points of commercial practice. There seems, therefore, no inherent harm in habitually enlisting the services of a small group of jurymen—at any rate for a coroner's jury where the juror's oath indicates that the jury's traditional functions are not quite the same as in

other tribunals. Coroners, however, will note that the King's Bench Division condemns the practice of restricting the panel of jurors. A second irregularity alleged in the Kingston-upon-Hull case was that the coroner joined the jury in their inspection and discussion of the damaged vehicle without allowing any of the parties to be present, and that he allowed a police constable to speak to the jurymen and to point certain matters out to them. The judges were of opinion that, while of course the jury were entitled to view the vehicle, and while the coroner was not doing anything wrong if he went with them, it was probably better that he should not. If he did go with the jury, he should carefully abstain from discussion of the case with them. The Hull coroner put in a sworn statement that he had so abstained and the judges accepted the statement. They did not take a serious view of this alleged irregularity; in particular they said that the complaint that other parties were not admitted to be present at the visit to view the vehicle had not been made out. In any case the coroner was not bound to admit them; it was a matter for his discretion. There was a third irregularity which the Divisional Court regarded as substantial—namely, that the police constable, who had already given sworn evidence in court as to the speed at which a particular motor-car was travelling (the one most material issue in the case), should have been allowed to give supplementary evidence to the jury outside the court. This the Divisional Court found to be a valid reason for quashing the inquisition for reasons very like those given in the North Mimms decision where the coroner's officer, also a witness, had accompanied the jurors in their retirement. A man against whom a verdict of manslaughter was ultimately returned by the coroner's jury would, said Mr. Justice Talbot, naturally feel that he had not been fairly treated if—as apparently happened—the foreman of the jury asked him questions obviously based on information obtained outside the court. One final allegation of irregularity was disregarded by the Divisional Court. It had been complained that the coroner was at fault in not reading over to the witnesses his notes of their evidence before they signed. On this point the judges observed that no doubt if a coroner thought there was any uncertainty as to what a witness had said, or if the witness requested it, the deposition ought to be read over, and the witness might be justified in refusing to sign until it was. But the statutory requirements are definitely stated in Section 4 (2) of the Act of 1887: the coroner is to put in writing the material parts of the statements made on oath, and both the coroner and the witness are to sign. The Divisional Court felt it had no right to add another positive requirement to those which Parliament had enacted.

A LOCUS CLASSICUS.

As was explained in our previous account of the Kingston-upon-Hull case, fresh evidence was disclosed after the first inquest. On this account alone the Divisional Court could, and did, order a new inquest last February, the second inquest being held in an adjoining division and resulting in a verdict of accidental death. Not content with this ground for quashing the inquisition, the Divisional Court decided to examine somewhat elaborately the various allegations of irregularity, which they found themselves able to do without making any reflection upon the coroner. Their decision is likely to be a *locus classicus* to which reference will be freely made in future. As the facts relate to practices in respect of which many coroners might regard themselves as having complete discretion, they deserve study. Taken together, the Kingston-upon-Hull and North Mimms cases are a warning that inquest procedure must conform, to a greater extent than was previously perhaps deemed necessary, with the orthodox methods of a criminal trial. The well-established popularity of the coroner's inquest might not protect it from the destructive consequences of a series of similar attacks suggesting that both the forms and the spirit of justice have been neglected.

Sale of Poison from Automatic Machine.

While revision of the law governing the sale of poisons still hangs fire, an important decision has been given in the Wood Green county court on the sale of bottles of lysol from an automatic machine. A friendly test action was brought some time ago by the Council of the Pharmaceutical Society against Harry Ronald Watkinson, a member of the Society, outside whose shop was an automatic machine containing such bottles. The bottles bore Mr. Watkinson's name and a statement that they contained 50 per cent. of cresol; they were labelled "Poison." The Society's contention was that an automatic machine is not a qualified chemist and that sale by such machine is consequently an illegal carrying on of the business of chemist and druggist. The Society naturally upholds the principle that it is undesirable that the public should have ready access to poisons without the supervision of a qualified chemist; the point is important in view of the greatly expanding use of automatic machines. The defendant conceded that the sale fell within his general supervision but was not within the particular degree of supervision requiring the purchaser to sign the poisons book. In May Judge Crawford reserved judgment; on June 26th he delivered judgment at Edmonton, holding the sale to have been illegal. The defendant, he considered, carried on the business of a chemist and druggist through the medium of an automatic machine, through which he sold to the public a dangerous poison. "In my judgment any other conclusion would be most unfortunate in the public interest." The judge was satisfied that any child tall enough to place a coin in the slot and take a bottle of lysol could do so without the knowledge of the defendant or any of his employees. "Beyond all question this ought not to be allowed to continue." The analyst's evidence had been that the bottles contained over 47 per cent. of homologues of carbolic acid. No supervision, said the judge, had been exercised over the sale. "The sale of such a dangerous poison as lysol certainly ought to be part of the business of a chemist and druggist rather than of any other trader." The court inflicted the statutory penalty of £5 with costs.

It is at first sight surprising to find a penal action of this nature taken in the county court. The machinery for recovering penalties is laid down in Section 12 of the Pharmacy Act of 1852 as "by plaint under the provisions of any Act in force for the more easy recovery of small debts and demands." Section 15 of the 1868 Act applies the 1852 Act machinery to the recovery of penalties under the later statute. On the general question of supervision of sales by persons having special professional training and qualifications it seems clear that, if Parliament requires such supervision as a necessary precaution, sale by a Robot is a breach of the law. The official volumes of criminal statistics (of which the volume for 1928 was recently published) do not give any serviceable figures of the number of crimes where poisoning is suspected or proved. The public, however, is aware of cases of poisoning, not always brought home to the criminal, where some readily obtained substance of the weed-killer type was apparently employed.

THE MARIE CURIE HOSPITAL.

THIS hospital was officially opened on Thursday in the presence of a distinguished gathering. The hospital, whose arrangements were fully described in our issue of March 8th (p. 527), is the outcome of a clinic started by the London Association of the Medical Women's Federation in 1925, in order to provide radium treatment for women suffering from cancer, particularly uterine cancer. Its chief aim is to advance knowledge of the methods of treating cancer by means of clinical research; close coöperation between a group of surgeons and the scientific staff is assured by the appointment of a research officer as director. The accurate record and study of results is the only means by which a trustworthy body of evidence can be built for future guidance; it serves also as the basis for modifications in technique. Sir Walter Fletcher, whose official position has given him special opportunities of following the progress in detail of radium treatment, has stated that nowhere in Great Britain is there available any series of results on such a scale properly recorded and extending for such a series of years as these. It is, he said, imperative in the national interest that observations, so well begun and continued, should be maintained and developed in order that treatment may be guided in the light of an increasingly secure foundation of ascertained knowledge.

The Marie Curie Hospital, which is staffed entirely by medical women, is now treating more cases of cancer of the cervix per annum than any other clinic in England; the number is, in fact, as large as those at present treated at the Fondation Curie in Paris, or at Radiumhemmet in Stockholm. The total number of these cases treated since the clinic was started is over 440. The method of technique which has, apart from minor modifications, been practically the same from the start, was described in detail in a report published last year.

At present there are only 30 beds in the hospital, but plans have been prepared for an addition which will be built when funds are available. The new wing is designed to provide more accommodation, including an X ray department and additional pathological laboratories. Our illustration gives a general idea of the building as it now is.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

A PUBLIC HEALTH POLITICAL PARTY.

A NEW organisation has just appeared on the horizon. It calls itself *Parti Social de la Santé Publique*. What makes one take it seriously even at this early stage are the characters of its president and secretary-general, Justin Godart and Dr. Georges Schreiber respectively. The latter is already well known in France for his tireless advocacy of the periodic medical examination in all walks in life. The appeal he has just sent out to the public to rally to his party is doubtless well suited to our mentality, so different from yours. The Englishman when he wishes his appeal to the masses to be really effective, says he is addressing every thoughtful and far-seeing person. Dr. Schreiber dispenses with flattery. He is abusive instead. He says:—

"The Frenchman, to be candid, has not, as a rule, the taste for hygiene. He has no more taste for it to-day than he had 30 years ago for exercise and sport.... The organisation of our public health services throughout the country is radically faulty. Our hygienic defences are only in an embryonic stage, our public health staff is much reduced and our public health budget is simply ridiculous."

The programme of this new *Parti Social* includes: (1) the inculcation of the taste for hygiene just as the taste for sport has been inculcated in the French nation; (2) agitation for legislative reforms in the field of public health; (3) creation of a budget corresponding to the public health needs of the nation; (4) provision of a properly equipped public health organisation throughout the length and breadth of France. With reference to this last item on the

programme, it is pointed out that as many as 23 departments possess no public heath organisation whatever, and that most of the others have such an organisation in only a most rudimentary form. The means whereby the party hopes to attain its ends include education of the public—notably at the time of the elections—the exercise of pressure on the members of the legislative and executive bodies, and roping in of the press.

B C G AND THE PASTEUR INSTITUTE.

The Pasteur Institute has issued to the press a communiqué about the Lübeck disaster, allocating the blame therefor in the following terms. "The French and foreign press have, in connexion with the Lübeck drama, given great publicity to the notion that the preventive tuberculosis vaccine, prepared by the Pasteur Institute and known as B C G had caused the death of many infants from tuberculosis in this town. It is proved by official investigations made by the Government of the Reich that these deaths are due to a fatal error of the laboratory of the municipal hospital of Lübeck which has substituted virulent cultures of tuberculosis for the harmless B C G. It is therefore necessary that everyone be informed that the B C G vaccine of Calmette and Guérin has nothing whatever to do with the matter, and has no responsibility for these accidents."

MEDICINE AND LITERATURE.

No one knows in France how many doctors there are who, having satisfied their examiners in medicine, have ceased to practise it and have turned to some more congenial and less arduous métier. We do not pay much heed to these apostates unless they distinguish themselves. Why should we? We know we have our potential novelists and poets, and we wait till the potential or incubation stage is over before we rush to claim them as long lost brethren. We have done this just lately in the case of Georges Duhamel to whom the "Forty Immortals" of the French Academy have allotted its "Grand Prix" for literature. It is, perhaps, unfair to speak of apostasy from medicine in his case, for the war showed him to be an excellent surgeon as well as an almost uncannily clever writer. He is most prolific—almost as prolific as Galen himself, but let us hope with a saner literary offspring. Among the best known of his works are "Le voyage à Moscou" and "Scènes de la Vie Future."

A WOMAN'S APPOINTMENT.

The recent promotion of Madame Bertrand-Fontaine to the staff of the public hospitals in Paris has been hailed as a new and signal triumph for the French woman. So it is. Other women will doubtless enjoy the same success from time to time in proportion as they deserve it; since the appointments are subject to the scrutiny of an open competition, the best man or woman (more or less and little accidents apart) should get them. Madame Bertrand-Fontaine's career, recorded in the *Siecle Médical*, has already been quite distinguished in spite of a digression into matrimonial life. The mother of two children, and aged only 34, she was appointed a hospital "externe" in 1920 at the first competitive examination after the war. Appointed "interne" in 1921, she worked successively under such leaders of the medical profession as Aglave, Hartmann, Ménétrier, Widal, Boidin, and Paisseau. Without having abandoned the highway of general medicine, she has devoted special attention to diseases of the kidneys, in the study of which she has been greatly helped and inspired by Widal. She has, in fact, started well.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

STATE CARE OF CHILDREN.

THE present municipal authorities of Vienna are Socialist, and it is interesting to note what they are doing for the welfare of children; the governing principle is "*produktive Fürsorge* (productive welfare work), not charity," and the aim is to turn out useful members of the community. Herbert Spencer has said that the education of a child begins 20 years before its birth, and in Vienna this theory has been acted upon. Apart from antenatal care a course of lessons in the hygiene and management of infants has been started for women and girls in a populous part of the city. The pupils practise on dolls until they have attained enough ability and knowledge to be trusted with live babies. For confinement women are sent to one of the maternity clinics or gynæcological wards, all of which are splendidly equipped and run by the municipality or the State. After the birth of the child, mother and offspring remain only a few days in the ward, and are then taken to a *Kinderheim* (children's home), where both are well looked after. Every new-born child is entitled to a complete outfit, which is furnished by the municipality free of charge. Breast-feeding is encouraged in every instance, especially in the *Kinderheim*. When mother and baby leave for home, she is obliged to bring it up for observation every month. If she has to work for her living and cannot trouble about her baby, a home is found for it, either with private people, who are supervised by welfare officers, or in one of the municipal institutes. When the child attains school age its care is entrusted to school doctors and specially trained welfare sisters, called *Fürsorgerin*. The general medical examination of the school child takes place as a rule in the first, third, fifth, and eighth years of its school life. The teeth are examined every three months at the school dental clinic, where also the child is taught to clean its teeth regularly. In the same way the school oculists look after eyesight, whilst periodical examination by the general medical adviser makes it possible to correct faults of general health.

Special care is taken of illegitimate children. Every child born since 1912 and having no legal representative—in other words, whose mother is not married—is taken under the guardianship of the *Jugendamt*, or official welfare centre for juveniles. These boards look after the interests of all the children born in Vienna until they have attained full age. The welfare worker, who is usually a young woman, has to see the child once a month. She has to report to the *Jugendamt* at least twice a year about the child, and is expected to supervise its health and make sure that it is not cruelly treated. One of the chief objects of the guardianship is to ensure the regular payment of an affiliation allowance fixed by the courts. In this country the father unwilling to pay may be imprisoned if the *Jugendamt* complains to the ordinary court.

"Productive welfare work" extends also to the child after his fourteenth year. As a rule, it is sent after leaving the public school to the *Berufsberatungsamt*, or advisory board for occupation. Examination of his mental and physical abilities gives a clue to vocation. Artisans and apprentices remain under the supervision of the *Jugendamt*, and there are legal restrictions of the duration and amount of work to

be expected from them. The maximum is eight hours a day, with no night work, and they must attend once a week for a whole day in apprentice schools, where they learn a trade. For at least two weeks yearly every juvenile occupied in a trade is sent to a recreation home.

TRACHEOMALACIA IN GOITRE.

At a recent meeting of the Wiener Gesellschaft der Aerzte Dr. Sgalitzer demonstrated a number of cases of a dreaded complication of goitre—namely, softening of the tracheal wall caused by pressure on the windpipe, with consequent atrophy of parts of the tracheal cartilage. Sometimes the walls of the trachea may give way and suffocation follows. The condition is not usually diagnosed promptly by the laryngologist, but X rays show that the lumen of the softened trachea is altered on coughing or sniffing. This method of examination under different pressures also gives satisfactory results in less obvious cases of diminished resistance of the tracheal wall. To know that the trachea is soft is very important when operating for goitre. With this knowledge the surgeon can operate with the tracheoscope in situ, or can do a preliminary operation. Examination of patients several years afterwards shows that tracheomalacia persists after operation, but there is relief from stenosis, and breathing is free. The lumen is usually normal or but little narrower; sometimes the trachea is even distended. Examination under different pressures shows increased motility of the walls, because the cartilage is not regenerated. The firm scar tissue acts as a support and prevents collapse of the walls.

In the present state of our knowledge, said Sgalitzer, it is necessary to study the condition of the tracheal wall in every case of goitre. It is just in the doubtful cases where the question of operation arises that the radiologist will be called upon to decide on its conditions.

ROYAL SANITARY INSTITUTE.

CONGRESS AT MARGATE, JUNE 21ST–28TH, 1930.

(*Continued from p. 43.*)

LAST week some account was given of an important discussion in the Section of Preventive Medicine. A report follows of two other topics which were warmly debated. To emphasise the catholicity of the gathering, the Council of the Institute entertained the overseas delegates to luncheon, at which Surgeon DANA E. ROBINSON (Washington), Dr. W. J. BELL (Ontario), and Dr. HARRY B. BURNS (Pittsburg) responded to an address of welcome by Sir GEORGE NEWMAN.

Maternal Mortality.

In the Section of Maternity and Child Welfare, Dame LOUISE MCILROY stated her conviction that criminal abortion was on the increase and was an important factor in keeping up maternal mortality and morbidity. She thought the increase was chiefly amongst married women.

A councillor from a northern industrial town, who described himself as an unregistered practitioner, was certain from the nature of the applications made to him that this increase was a fact and affected both the married and unmarried. He knew, the police knew, and it was common knowledge, where these illegal operations were carried out. He suggested that police raids might do some good. After the school age had been raised he thought more education should be given in sex matters.

Another councillor, a retail chemist in London, said that he sold appliances such as gum-elastic catheters, which he felt certain were to be used for this purpose. He was convinced that Prof. McIlroy had understated the evil and he went on to refer to the huge sale of pills, obviously for use as abortifacients, by reputable drug firms. He would like to see the Pharmacists Union and the medical authorities combine to put a stop to the sale of these drugs. It was the unqualified chemist who was the stumbling block.

Prof. McIlroy said the police would be unable to get evidence to justify their raids and suggested that the pharmacists should themselves take steps to get rid of unqualified competitors as the doctors had done. They must look to the law to find the means of stopping the sale of these drugs and appliances. In the meantime the remedies which she suggested were a better moral outlook and a realisation by the public of the dangers of abortion and its effect upon mortality and health. Confidential notification of all abortions might give some idea of the prevalence of the practice.

Alderman HEPPENSTALL (chairman of the Twickenham Health Committee) said it was impossible for the police to get evidence upon which they could act. Drugs which were harmless or useful in small doses could not be ruled out. Only propaganda was left.

Birth control was advocated by one speaker as a preventive and Dr. STELLA CHURCHILL remarked that the expectant mother living with her family of seven in one room (mentioned by a previous speaker) was a fit object for therapeutic abortion.

SCOPE OF PREVENTION IN OBSTETRICS.

Dr. C. S. LANE-ROBERTS gave a lucid description of the aims of preventive midwifery, and Dr. LEONARD COLEBROOK a frank exposition of the gaps in our knowledge of the bacterial causes of puerperal fever. He showed a model of the new unit at Hammersmith of Queen Charlotte's Hospital, shortly to be opened, with its wards for 30 patients with puerperal infections and research laboratories fitted to accommodate several research workers, and made an appeal for other similar enterprises. We had, he said, the men for the research but not the money. He showed how our present knowledge might be applied to greater advantage.

Dr. S. G. MOORE suggested that while this bacteriological research work was in progress other local authorities would find it useful to adopt the Huddersfield scheme. Voluntary notification of pregnancy was there followed by a visit to the home and supervision by a woman doctor. Expectant mothers using these facilities had increased in number from 11 to 50 per cent. and the mortality among them had been reduced to one-third.

Hygiene on Ship-board.

At a conference of Port Sanitary Authorities, Lieut.-Commander H. J. CAVILL, of the Shipping Federation, Ltd., gave a description of the accommodation for the health and comfort of seamen which might be provided for the crews in merchant ships in spite of limitations of space. His assurance that shipowners as a whole were keenly alive to the improvement of crews' quarters aroused dissent.

Dr. J. HOWARD-JONES (M.O.H., Newport) said we were far behind many continental countries. A few British owners insisted on proper accommodation being made for the crews by the naval architects; most were content with the expression of pious opinions. The accommodation provided was uncomfortable and often wasteful of space. The Royal Sanitary Institute, the Society of Medical Officers of Health, and the Association of Port Sanitary Authorities had appointed a standing committee to press for reform but so far the Board of Trade had remained content to let compulsion wait on persuasion.

Dr. F. MCCALLUM (Chief M.O., Commonwealth of Australia) stated that their medical officers saw the plan of every ship before it was laid down. They always insisted on good washing and other accommodation; he believed their requirements were in advance of the rest of the world.

Dr. W. F. DEARDEN described Manchester as a typical port for medium-sized ships. He had kept records for two ten-year periods. During the first, British ships were in a good position, but during the second decade many foreign-built ships were far ahead of the British, and during the last two or three years some of the new British ships were worse than they were in the second decade. The British Government had no power to prescribe a standard. The Scandinavian standard, which was very high, was only reached by some British ships.

Dr. C. F. WHITE (M.O.H., Port of London) explained that Commander Cavill could not reply to criticisms as he was a member of the Committee of the Shipping Federation, which had this matter under consideration. He felt sure his hearers would be well satisfied when they read the recommendations in the report about to be issued.

Dr. L. W. HARRISON described a course of treatment for venereal diseases, which he had devised to suit the special circumstances of seamen, with a minimum of interference with their occupation. The course would be administered partly by the 300 V.D. clinics established in ports throughout the world under the Belgian Agreement and partly by the ships' surgeons. This scheme was now under the consideration of the expert Committee of the League of Nations.

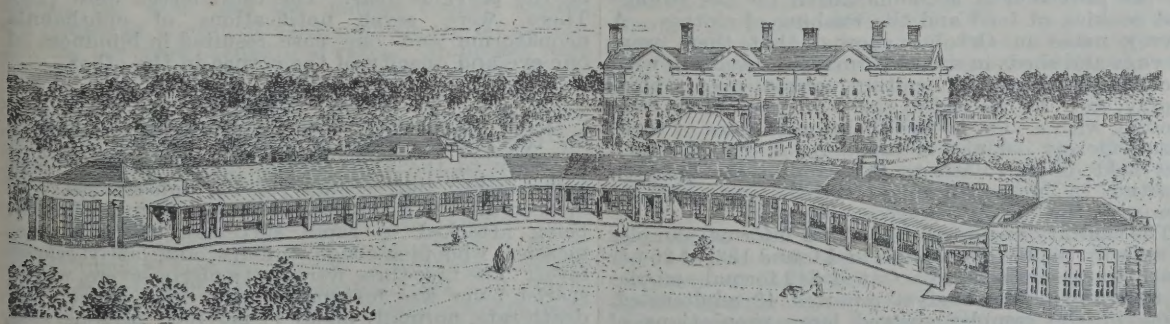
DERATISATION.

Dr. E. R. PEIRCE (Assistant Port M.O., Liverpool) dealt with article 28 of the International Sanitary Convention requiring the deratisation of ships. He described the elaborate method adopted in Liverpool for estimating the rat population in ships by counting the rat droppings during 24 hours after the ship had been swept. Due regard had to be paid to the diet of the rats. Dr. Peirce gave examples to show that a high degree of accuracy was obtainable; there was, he said, very close correspondence between the estimates made and the number of dead rats found after fumigation. He claimed that this system had added a new interest to work which was apt to be monotonous and that the estimations were keenly watched and a healthy rivalry established among the men. In reply to a question, Dr. Peirce stated that no standard had been laid down as to the number of rats on a ship which justified the expense of deratisation. They found it safer in most cases to fumigate than to give a certificate of exemption.

A MODERNISED NURSING HOME.

THE Haslam Nursing Home at Bolton, the opening of which was mentioned in a recent issue of this journal, is intended to supply accommodation for persons of small and moderate means as well as for the more well-to-do class of patient. It was at first proposed to build in the grounds of the existing infirmary, but on further consideration it was decided to add to Newlands, a house which had formerly belonged to the late Mr. J. P. Lord. The old building has been converted into the administrative department and nurses' home, and is connected with the patients' quarters by a block of buildings containing the kitchens and staff dining-rooms. The patients' quarters lie round three sides of a hexagon, open towards the southern aspect, and forming a long one-storey building from which 22 single rooms and two four-bed wards open on to a glass-roofed veranda. Bathrooms are attached to each wing and to one or two of the single bedrooms. The operating theatre and X ray installation lie behind the patients' quarters, and detached from the main building except for a connecting corridor. The home stands in about six and a half acres of wooded grounds sloping to the south, with a wide stretch of turf before the veranda. Furniture, paint, and equipment are all of the most recent type, and designed to save labour; central heating has been installed. Fees will vary from 4 guineas a week in the wards to 7 or more guineas, up to 12 in the private rooms; patients will be attended by their own medical men while in residence. The home, which is the gift of the Haslams and the Scotts, two Bolton families, is likely to prove valuable to many of those patients who do not fall into the hospital class, but whose means are insufficient to meet high fees.

HASLAM NURSING HOME.



Showing addition in the form of a one-storey pavilion.

PUBLIC HEALTH SERVICES

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1929 statistics of three county boroughs, a united county district, and three boroughs.

Name of district and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.

Registered stillbirths per 100 live births: Nottingham 4·7, Northampton 3·8, West Bromwich 2·9, Gillingham 4·3, Colchester 3·6, Stafford 5·4.

Nottingham.

Dr. Cyril Banks, who was appointed in January, 1929, submits a short report in view of the comprehensive report for the years 1916–28 submitted by the late Dr. Boobbyer, and the fact that 1930 is the year for a survey report. Nottingham suffered severely from the influenza epidemic. The death-rate from respiratory disorders showed a large increase. The general death-rate was 2·0 higher than the average for the previous five years. For a similar reason infant mortality went up from 85 to 96, and the tuberculosis death-rate was also increased. Changes have been made in the staff. A new chief sanitary inspector has been appointed and the city has been divided into seven districts for sanitary and housing inspection. It is hoped to deal, at an early date, with the unhealthy districts scheduled by the late medical officer. The industrial smoke problem will also receive more attention. The course of lectures for stokers delivered early in 1930 at University College was well attended. Steps are being taken to improve the "farmed out" houses by the provision of accommodation for the storage and cooking of food and the washing of clothes. A survey made in October showed that there were 93 vans and sheds in use as permanent dwellings with a complete absence of sanitary conveniences, water-supply, &c. At the end of the year proceedings were pending with a view to the abolition of some of these unsatisfactory colonies of vans. A national rat week was held on Nov. 4th to 9th, and it is hoped to institute a more thorough continuous anti-rat campaign throughout the year.

The sanitary inspectors tested 732 informal samples of milk by the Gerber process and found 183, or 25 per cent., to be adulterated. Out of 342 formal samples of milk the public analyst reported 43 adulterated. Some of the samples showed large proportions of added water and others high percentages of fat-deficiency. Proceedings were taken in respect of 15 samples. Three cases were dismissed, and in the remainder comparatively small fines were inflicted. During 1929 the average duration of stay in hospital for scarlet fever was 35·4 days, the figure being kept high by a few cases, which remained in for a very long time. The average stay in 1919 was 73·7 days, and in 1928 it had fallen to 43·6. Scarlet fever has been mild during recent years, and the use of the anti-toxin has further helped to shorten the stay in hospital. The venereal diseases clinic has been greatly improved during the year.

Northampton.

Dr. Stephen Rowland reports that the chief event was the presence of small-pox during the whole year. There were 479 notified cases, but many cases were concealed, and there was much opposition to the vaccination of contacts. The only death was that of a female, aged 59, vaccinated in infancy, and with four visible marks. She was admitted to hospital in a debilitated condition having suffered for years from large foul-smelling ulcers on both legs, and her case was complicated by acute laryngitis. The bacteriological examination of the town's water-supply shows considerable variation from time to time without apparent cause. Sometimes, when coliform organs were found in 5 c.cm., the total bacterial count was quite low. A small outbreak of enteric fever was considered to be due to the contamination of "Jubilee well," Kingsthorpe. Eight genuine cases from four houses which all used the well water occurred, but none of them was severe. The bacteriologist's report was unconvincing and the water appeared to be as pure as the town's supply. It was considered that the well water might have been infected during some drainage operations in the neighbourhood.

No slum clearance on a large scale was started during the year, but when, in the near future, the old destructor is demolished, a large area will be available for the erection of a small type of house similar to some municipal houses already built. Many families, says Dr. Rowland, cannot pay the rent for the expensive semi-detached houses on the outskirts of the town, together with travelling expenses to and from their work. He instances the case of a labourer earning 45*s.* per week, with a large family, and ordered to abate the overcrowding. This man was offered a corporation house at 15*s.* per week, but no philanthropist was forthcoming to act as guarantor.

Dr. Rowland has a good deal to say about the exaggerated claims made for artificial sunlight treatment. Of 18 cases of non-pulmonary tuberculosis treated at the General Hospital 14 were reported to be improved, and Dr. Evelyn F. Bevington claims that the children suffering from rickets, debility, &c., and treated with artificial light at one of the centres showed marked improvement. Two antenatal clinics are in operation, one being held at the Queen's Institute of District Nursing. The new cases attending these clinics numbered 585, a considerable increase on the previous year. The total births were 1249. There were seven notifications of ophthalmia neonatorum and one case resulted in blindness of one eye and opacity of the cornea in the other.

West Bromwich.

Dr. W. Stott says 1929 will be marked in history for two totally different reasons. Firstly, as preparatory to the vast changes to be made in local government; and, secondly, as the unhealthiest year on record. The town was never free from epidemics, being attacked in rapid succession by influenza, measles, whooping-cough, mumps, and lastly scarlet fever. The first three were particularly severe, whilst scarlet fever was fortunately of a mild type. The death-rate, normally about 11 per 1000 persons, rose rapidly in the first quarter to 46·2 in the beginning of March. Measles and whooping-cough have been

made notifiable. Dr. Stott hopes that the committee will admit severe cases of these diseases to the Fever Hospital. The infant mortality-rate "again passed the 100 mark" owing to the almost simultaneous outbreaks of influenza, measles, and whooping-cough, and the very high death-rate among young children was due to the same cause.

Systematic house to house inspections have been carried out, including 1991 houses, which were inspected six to nine years previously, so that a comparison with present-day findings is interesting. The population in the 1991 houses has fallen from 9432 to 8898, the number of multiple occupancies from 298 to 254, and the number of instances of overcrowding from 133 to 118. It therefore looks, says Dr. Stott, as if matters were slowly improving. Another interesting comparison is given of the conditions found in 86 privately erected subsidy houses, nearly all owner-occupied, and 32 houses belonging to the corporation. The population of the 86 privately owned was 294, or 3·6 persons per house; in only three was there more than one family, and only one house was overcrowded. In the 32 corporation houses there were 239 persons, or 7·5 per house; there were 12 cases of multiple tenancy and 5 cases of overcrowding. The corporation by their by-laws prohibit subletting, but do not attempt to stop it. Anyone, whether clean or dirty, may become a subtenant, and in some cases the subtenants pay the total rental. The corporation houses "are gradually becoming new slums." Dr. Stott's remedy is that the corporation should allow subletting on conditions. Every subtenant should be approved; there should be no subletting to produce overcrowding; the rent of the subtenant should be fixed by the committee, and when subletting is permitted the total rental should be made an economical one.

A scheme has come into operation by which the midwives are paid 1*s.* for a report on the character of the labour of all cases attending the antenatal clinics. The new cases attending the five antenatal clinics number 261, the total births being 1682. Only a few of the midwives as yet send their cases to the clinics.

East Kent.

The united district extends about 20 miles along the north coast of Kent from the North Foreland to Whitstable, and is bounded on the south by the River Stour and the city of Canterbury. It includes the whole of the Isle of Thanet, with the exception of the boroughs of Ramsgate and Margate. It consists of the two urban districts of Broadstairs and St. Peter's, and Herne Bay and the two rural districts of Thanet and Blean. Dr. A. M. Watts shows that during 1929 the deaths exceeded the births in the district as a whole, but were lower than the births in the two rural districts. The summer population of the two urban districts is about doubled by visitors, who also patronise the rural districts. In the two rural districts agriculture is the main occupation, but in Blean there is a colliery (Chislet) employing 1000 men, and the Manston aerodrome is situated in Thanet, with 80 officers and 1200 men. In Blean rural district 100 houses were completed by the colliery during the year, and the district council erected 12 houses at a cost of £4624, which are let at 11*s.* and 9*s.* per week exclusive of rates. No houses were erected in Broadstairs urban district, but Dr. Watts has advised the council to build, as there are several houses needing demolition, and at the end of the year the council advertised for applications from persons who desired municipal houses. Referring to the high rentals in this district, Dr. Watts points out that if working people have to pay 25 to 50 per cent. of their income in rent and rates, they have to go short of necessaries, and to be assisted out of public funds in case of sickness. Thanet rural district includes two parishes, Westgate-on-Sea and Birchington, which are governed by parish councils reinforced by the rural district councillors of the parish. Sixty houses were built in Thanet during the year, 14 being in Westgate and 28 in Birchington. Only about 18, however, are suitable for the working classes. Five applications were received in Thanet under the Housing (Rural Workers) Act, and grants were allowed for four of them.

Diphtheria was more prevalent than in the previous year. There was an outbreak in connexion with a school in the Blean district. The exclusion of children by swabbing and the measures of disinfection carried out appeared to be effective. Private schools, institutions, and convalescent homes in this district are responsible for a large proportion of the cases of infectious disease notified. Efforts are being made to induce these institutions to provide temporary isolation accommodation, and in two instances in Broadstairs this provision was made. The isolation hospital accommodation for the Isle of Thanet is inadequate, and will no doubt come under the purview of the county council under the new Local Government Act.

Gillingham.

Dr. W. A. Muir reports that more commodious office accommodation has facilitated the work of the department. Two new child welfare centres have been opened in the borough, and it is hoped to give increasing attention to the pre-school child. There were two notifications of small-pox in April. One was of the mild type and the other, a passenger from s.s. *Tuscania*, died from hæmorrhagic small-pox. Rooms are sprayed with formalin after the removal or death of cases of pulmonary tuberculosis and enteric fever, but in the case of scarlet fever and diphtheria thorough cleansing is relied upon. Of the eight notified cases of ophthalmia neonatorum there was one case of serious impairment of vision and possibly total blindness, notwithstanding prompt hospital treatment. The council erected 133 houses during 1929. The rentals, including rates, ranged from 13*s.* 4*d.* to 11*s.* 2*d.* per week. Although the unskilled labourer cannot pay these rents, Dr. Muir considers that he benefits by "moving up" to a better vacant house.

Colchester.

Dr. W. F. Corfield thinks the infant mortality-rate of 26 is probably the lowest ever recorded for a town the size of Colchester. The total deaths showed an increase of 73 on those of the previous year, the increase in heart disease being 53. Many of the latter were accelerated by the influenza epidemic. There were 15 deaths of residents and non-residents from motor accidents in the borough during 1929. The appointment of a full-time dentist has enabled a weekly clinic to be established for expectant mothers and young children. The subsidised new houses numbered 147, and the housing shortage is being overtaken. There are a number of worn-out houses which ought to be closed. The landlords say they are not worth spending money on, and are being asked to accept tenants without children as a makeshift for the housing of elderly people until houses at an all-in rate of from 4*s.* to 8*s.* a week are available. For three years the prevalence of diphtheria has been very low, 7, 8, and 10 cases, but in 1929 there were 47. Dr. Corfield discusses the unaccountable behaviour of this disease. Scarlet fever cases are discharged during the fifth week, if free from complications. Of the six "return" cases which occurred two were the brother and mother of a child who had been in hospital for 143 days.

Stafford.

Dr. J. T. Macnab reports that the influenza epidemic in his borough was followed by whooping-cough and by measles in the latter half of the year. Further housing schemes are to be undertaken, and it is hoped that overcrowding and the closure of the worst houses will then receive attention. The reservation of 40 municipal houses for families nominated by the Health Department has done much to relieve serious overcrowding in unhealthy surroundings. No less than 160 children, 70 of whom were under

5 years of age, were thus removed from very unsatisfactory conditions to a good environment on the new estate adjoining the common. There are about 80 houses needing demolition and 20 more families living overcrowded. In most of these 100 cases the rentals are about 5*s*. Mechanical filtration is being installed for the swimming bath and should be in operation during 1930. The inspectors are experiencing much difficulty in tracing the pollution of water courses by oily substances. Stafford has adopted the model by-law for smoke abatement on the recommendation of the Midlands Joint Advisory Council, but it is expected that there will be difficulty with the salt works, where one of the chimneys serves 12 furnaces. There are two modern slaughter-houses and 13 old ones in quite unsuitable surroundings. The needs of the town would be well met if there were a third modern establishment to do the work of the 13 older ones.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JUNE 28TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 182 (last week 241); scarlet fever, 1630; diphtheria, 1114; enteric fever, 86; pneumonia, 605; puerperal fever, 39; puerperal pyrexia, 88; cerebro-spinal fever, 14; acute poliomyelitis, 5; acute polio-encephalitis, 2; encephalitis lethargica, 14; continued fever, 1; dysentery, 5; ophthalmia neonatorum, 93. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on July 1st–2nd was as follows:—Small-pox, 354 under treatment, 6 under observation (last week 399 and 9 respectively); scarlet fever, 1834; diphtheria, 2019; enteric fever, 23; measles, 448; whooping-cough, 76; puerperal fever, 22 (plus 13 babies); encephalitis lethargica, 122; "other diseases," 16. At St. Margaret's Hospital there were 10 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (0) from enteric fever, 17 (3) from measles, 4 (2) from scarlet fever, 12 (1) from whooping-cough, 26 (5) from diphtheria, 43 (9) from diarrhœa and enteritis under two years, and 10 (1) from influenza. The figures in parentheses are those for London itself.

No great town had more than 2 deaths from measles; Liverpool and Stockton-on-Tees reported 2 each. Two fatal cases of diphtheria were reported from each of West Ham, Bristol, Birmingham, Coventry, and Liverpool. Diarrhœa was responsible for 4 deaths at Portsmouth and 3 at Manchester.

The late returns for the month of May include 2 deaths from small-pox assigned to Newark M.B. (Notts), and Bedwellty, U.D. (Mon.). In addition, a death belonging to Stoke-on-Trent C.B. occurred outside that area during the week ended May 3rd.

The number of stillbirths notified during the week was 323 (corresponding to a rate of 45 per 1000 births), including 37 in London.

CORRESPONDENCE

CHOLELITHIASIS AFTER BLACKWATER FEVER.

To the Editor of THE LANCET.

SIR,—All students of tropical medicine will be interested in reading Dr. Keith Fairley's paper in your issue of June 28th. The case he quotes is apparently the first in which actual proof was obtained of the formation of pigmented biliary calculi as the direct sequel of inspissation of bile and the result of the hæmolysis of blackwater fever. It aroused my attention because I have recently met with an instance of recurrent biliary colic in one of my patients recovering from a severe attack of blackwater fever. This patient, an assistant in a business house, was employed in the Cameroons, and was seen by me for an attack of malaria on Oct. 12th, 1929, and was ordered to take grs. 10 quinine hydrochloride daily. On the evening of Nov. 9th, 1929, he suddenly developed an acute attack of blackwater, and on the next day was admitted to the Hospital for Tropical Diseases. Treatment consisted of a preliminary intravenous injection of 1 pint of sodium bicarbonate (grs. 150 to the pint), followed the next day by a blood transfusion of 350 c.cm. He made a very rapid recovery so that within four days the jaundice had cleared away. On Nov. 30th, three weeks after the advent of blackwater, he had a series of typical attacks of biliary colic each lasting ten minutes, and requiring injections of morphia for their alleviation. Ten days later there were further attacks accompanied this time by obstructive jaundice. Still more attacks were noted in December and early in January, 1930, when they became less frequent and less severe till they finally passed away. It was assumed that he had passed biliary sand in each of the attacks, and that they were due to inspissated bile-pigment in the gall-bladder. In this case no direct assistance in the diagnosis of cholelithiasis was obtained by the tetra-iodo-phenolphthalein dye test, or by attempts to visualise the gall-bladder by means of X rays.

I am, Sir, yours faithfully,

PHILIP MANSON-BAHR.

Weymouth-street, W., July 2nd, 1930.

METABOLISM IN BLACKWATER FEVER.

To the Editor of THE LANCET.

SIR,—I have read with deep interest Dr. Donald Hunter's Goulstonian Lecture on the Significance to Clinical Medicine of Studies in Calcium and Phosphorus Metabolism in your issue of April 26th, and it is with great diffidence that I offer a suggestion, based on the above paper, on the pathology of blackwater fever. My excuse is that any avenue of approach which might help to throw light on this malign manifestation is deserving of consideration.

Has any worker hitherto investigated the question of phosphorus metabolism and the influence of phosphatase in this connexion? It is well known that certain organs are not infrequently attacked by the malaria organism—e.g., an involvement of the intestine results in abdominal signs, that of the brain in cerebral malaria. The subjects of blackwater are usually under-nourished. During the war I had occasion to attend over 90 cases of blackwater which occurred among the Indian troops who at the time were so situated that no fresh food, meat, milk, eggs, or vegetables were available. The diet consisted of rice, ghee, wheat flour, and lentils. In other words, the rations lacked in great measure phosphorus. May it not be that in a certain proportion of malaria cases the parathyroid gland becomes involved and stimulated to increased activity, which would result, presumably, in a lowering of the phosphorus threshold,

and thus, in the circumstances described, render the phosphoric esters of the red blood corpuscles unstable and easily prone to disintegration by the combined action of phosphatase and the demands of the hæmamœba for nutriment? The concentration of phosphatase in quantity in the cortex of the kidney might explain the mechanism of suppression.

This view may account for the beneficial results claimed in the treatment of blackwater fever, with intravenous injection of sodium acid phosphate, its irregular geographical distribution, and the reason why some suffer while others do not. It would be interesting if Dr. Hunter were kind enough to find time to criticise this speculative theory.

I am, Sir, yours faithfully,

J. O. SHIRCORE,
Director of Medical and Sanitary Services,
June 11th, 1930. Tanganyika Territory.

STRAMONIUM IN THE TREATMENT OF MUSCULAR RIGIDITY.

To the Editor of THE LANCET.

SIR,—As no comment has been made in your correspondence columns on the dose of stramonium recommended by Dr. C. Worster-Drought and Dr. T. R. Hill in their most interesting and valuable paper (June 7th, p. 1225), I feel it is desirable that a note of caution should be sounded. A dose one-third the size of that recommended is liable to cause unpleasant symptoms in not a few patients when given for asthma, and I have found that 15 to 20 minims thrice daily is a maximal dose for general use. Personally I have not used stramonium for the muscular rigidity of parkinsonism, but for 30 years I have freely used the less active tincture of hyoscyamus for the similar type of rigidity which is the cause of tonic hardening of the colon; or, as it is now sometimes called (and I believe incorrectly), "spastic" colon. This drug in 20-minim doses when combined with an intestinal antiseptic is most potent in controlling the abnormal muscular activity and in arresting the mental depression, obsessions, or other symptoms which may characterise this ailment. Tincture of hyoscyamus, in 20-minim doses given thrice daily, is, however, sufficient to do this and, not infrequently, even this dose causes dryness of the throat or other unpleasant symptoms. I feel sure that to give three times daily 60 minims of the more potent tincture of stramonium would not be wise as a general rule.

I am, Sir, yours faithfully,

Birmingham, July 1st, 1930. T. STACEY WILSON.

THE REMOVAL OF NON-MALIGNANT TUMOURS OF THE BREAST.

To the Editor of THE LANCET.

SIR,—The learned, practical paper on this subject by Mr. Greenwood, published in your issue of July 5th, gives me the opportunity of making myself clear upon the question of so-called "chronic mastitis." Two separate conditions are confused within this single term. Neither of the two conditions would be accurately described by the application of this term.

The first state is that in which the terminal ducts and acini are surrounded by hyperplasia of the peri-canalicular and periacinous connective tissue, amongst which lymphocytes and macrophages may be present. There is often a desquamative epithelial hyperplasia of a very definite type in the affected ducts and acini. It is a very common and almost universal state in all breasts of women who have borne children. It also appears, but less commonly, in virgins. The same morphological appearances are seen normally in the breasts of male and female children at birth, in girls at puberty, and in breasts of pregnant women, and during lactation. It is almost a physiological condition and ceases to give rise to symptoms at the menopause. Cysts are not formed as a part or sequence of this state. The only lesion that can be directly traced to this state is the formation of a certain type of fibro-adenoma. This condition is so universal that the oxygen we breathe is just as impossible a factor to trace as an actual or predisposing cause of disease. Mazoplasia is the term I would apply to this condition.

The second condition, and a much more important one, that is included in the term "chronic mastitis" is the lesion best known as "Schimmelbusch's disease" or "maladie reclus." It also affects terminal ducts and acini, and in its earliest stage a specific type of desquamative epithelial hyperplasia occurs that cannot be mistaken for anything else, and forms the common cysts of the breast. The epithelial hyperplasia may pass into a state of epithelial neoplasia, at first benign, which may become carcinomatous, and does so in at least 20 per cent. of all carcinomata of the breast.

I would venture to suggest the advisability of dropping the term "chronic mastitis" altogether. It would make the path of the student more free from obstruction if the first state were called "mazoplasia," and the second "Schimmelbusch's disease."

In the *Cancer Review* of February, 1930, the two states are described in detail, and I respectfully advise all who are interested in this matter to read the article I wrote therein upon Precancerous Conditions of the Breast.

I am, Sir, yours faithfully,

G. LENTHAL CHEATLE.
Harley-street, W., July 4th, 1930.

NOISE IN HARLEY STREET

To the Editor of THE LANCET.

SIR,—I am glad to see that Sir Thomas Horder and others have taken up the question of the devastating din that is being produced in the building of the London Clinic. I have the misfortune to live within 100 yards of this appalling row; and it has meant during all this hot weather that conversation, telephoning, or the use of the stethoscope have been quite hopeless without closely shutting up all the windows. Even then the irritation is nothing short of intense.

The one redeeming point about it is that it has brought home to me—much more forcibly than politely—the effect of noise on the nervous system. It is almost unbelievable; people who are otherwise placid and unruffled become irritable and tired. The strain of this din going on all day long acts as a powerful irritant to the nervous system. If any medical man would care for proof of this he is quite welcome to half an hour in my consulting room with a stethoscope, or even to try a call or two on the telephone, with the windows open.

By day Marylebone-road is one of the noisiest in London; by night, owing to the heavy type of traffic that passes through, I should say it is, without doubt, *the* noisiest street in London. But why we should be tortured by this extra and avoidable infliction without registering a pretty vigorous protest I do not know. Unless something is done pretty

quickly to mitigate this serious nuisance, I fear the sympathetic support mentioned by Sir Thomas Horder will be gravely imperilled in a good many cases. I am, Sir, yours faithfully,

A. GRAHAM-STEWART.

Ulster-place, Upper Harley-street, N.W.,
July 4th, 1930.

THE RAPID CURE OF SCHISTOSOMIASIS.

To the Editor of THE LANCET.

SIR,—Late vomiting and gastric disturbance were so pronounced in two cases of bilharzia disease treated as out-patients at Durban in January last with neo-antimosan or fouadin, that the drug was discontinued in one of the patients after the third dose. The other patient was able to stand a total of 53·5 c.cm. in 31 days, but was continually complaining of indigestion and late vomiting, and showed a badly furred tongue throughout. Unfortunately, the normal ovum of *Schistosomum hæmatobium* was present in the urine three months later and the urine was frequently bloodstained. A colleague was therefore requested to test fouadin in the treatment of some native bilharzia patients he had as in-patients, and he did not observe any such toxic effects from the doses that are recommended.

The box containing the ampoules of fouadin with which the toxic symptoms were associated, was returned to Messrs. Bayer Ltd., who reported that no change had occurred in the chemical nature of the contents, and that the toxicity coincided with that of the standard preparation. The question arises whether the destruction of these large blood parasites by a drug which causes their too sudden death may not be responsible for the formation of septic foci in the liver substance or other site away from the mesenteric veins which would seem to be a favourite site for the living bilharzia worms.

I am, Sir, yours faithfully,

F. G. CAWSTON, M.D. Cantab.

Durban, Natal, June 17th, 1930.

RETROBULBAR NEURITIS AND DISSEMINATED SCLEROSIS.

To the Editor of THE LANCET.

SIR,—May I add the following case to those recorded by Dr. C. P. Symonds in your last issue, emphasising the necessity for regarding all cases of retrobulbar neuritis, in which no ætiology is found, as potential cases of disseminated sclerosis? In his series the longest interval between the ocular symptoms and the development of other signs appears to be sixteen years. In the following case *twenty-two* years elapsed before further symptoms of disseminated sclerosis developed.

Mrs. X., aged 43 years, was referred to me by Dr. T. St. John Barry, of Wallasey. When 18 years old she suddenly lost the sight of the left eye, and before this had completely recovered she lost the sight of the other; both eyes recovered completely in a few months. She thinks she experienced transient numbness of the right leg at this time. No further neurological symptoms developed until three years ago, when she noticed weakness in the lower limbs, and unsteadiness of gait. Two years ago she lost anal and vaginal sensation for a month, since when she has had precipitance of micturition and occasional incontinence of urine. On examination her optic discs show definite temporal pallor; she has slight lateral nystagmus, a spastic paraplegia, absent abdominal reflexes, and diminished vibration and joint sense in the lower limbs—a typical clinical picture of disseminated sclerosis.

But the initial symptoms in disseminated sclerosis, other than ocular, may precede the more marked development of the disease by an equally long period. Thus, in one of my cases, a "useless right arm" developed in 1903, associated with numbness of the left leg, and no further symptoms appeared for 25 years. All such cases provide interesting comment on the difficulty of assessing the value of so-called specific treatments in this disease.

I am, Sir, yours faithfully,

Liverpool, July 5th, 1930. HENRY COHEN.

OBITUARY

GEORGE NEIL STEWART, M.D. Edin., D.P.H.,

PROFESSOR OF EXPERIMENTAL MEDICINE IN THE WESTERN RESERVE UNIVERSITY, CLEVELAND.

WE regret to record the death of Prof. George Stewart, the well-known physiologist and worker in experimental medicine, which occurred on May 28th last in Cleveland. He had been suffering for some time from a condition which had been diagnosed as pernicious anæmia.

George Neil Stewart was born in London, Ontario, where his father, James Innes Stewart, resided, and where he received his preliminary education. He entered the University of Edinburgh, and having graduated with mathematical honours joined the medical school. He was a highly distinguished student, being Neil Arnott scholar and prizeman, Mackay-Smith scholar in physiology, and Bell and Goodsir prizeman in the same subject. In 1889 he became D.Sc., and two years later graduated in medicine with the gold medal. Thereafter he did post-graduate work in Berlin, Strassburg, Aberdeen, and Cambridge, being George Henry Lewes student at the last-named University, where he also obtained the diploma of D.P.H. In 1894 he was elected professor of physiology in the Western Reserve University, Cleveland, a post which he held for nine years, when he accepted the post of professor and director of the physiological laboratories of the University of Chicago. This post he held till 1907, when he returned to the Western Reserve University as professor of experimental medicine and director of the H. K. Cushing laboratory, posts which he held at the time of his death.

From this summary it may be gathered how wide and practical Prof. Stewart's labours in his specialty were, a fact which was reflected both in his manual of physiology, the eighth edition of which was published 12 years ago, and in his contributions to the *Journal of Experimental Medicine*, the *Journal of Pharmacology and Experimental Therapeutics*, and various contributions to the Proceedings of the Royal Society of Edinburgh and other learned bodies. He was, indeed, one of the most prominent exponents of experimental pathology in the United States, and his death leaves a gap in the ranks of research workers.

Prof. Stewart's end was sadly sudden. On the morning of May 28th he was found in a state of coma in his apartments, and efforts to make a blood transfusion failed, for he died before a donor of the proper type could be secured. He leaves a wife and four children who are resident in Toronto, where his ashes were taken for burial after cremation.

JOHN JEROME SUCKLING, M.B.Lond.

Dr. J. J. Suckling, who died at his home in Margate on June 24th, was the son of Dr. C. W. Suckling, consulting physician to Queen's Hospital, Birmingham. Educated at University College Hospital, London, he qualified in 1908, and held house appointments at his hospital before settling in practice at Margate, where he was successively in partnership with Dr. Scales and Dr. Gosset. "By his early death," writes a colleague, "Margate has sustained a serious loss, for Suckling was one of the best type of family doctor—reliable, courteous, and conscientious. He had a fine all-round knowledge of general practice, and in midwifery he excelled owing to the care he took to see that all was right before, during, and after confinement. Though never blessed with robust health nothing ever seemed a trouble to him, and to the younger men his was always the helping hand; for he had a shrewd knowledge of humanity and his advice was always sound and to be trusted." Death was due to an acute lobar pneumonia. Dr. Suckling leaves a widow.

PROF. MATTHES.

Dr. Max Matthes, who died at Meran on March 26th, was professor of internal medicine at the University of Königsberg and well known for his "Lehrbuch der Differential-diagnose Innerer Krankheiten" which ran through six large editions and was translated into English, Spanish, Russian, and Czechoslovakian. His junior colleague, Dr. Rudolf Wigand, has sent us an appreciation of his life and work.

"Matthes," he writes, "was a man of untiring activity, always willing and ready to study, to learn, to help, and to discover something new. His understanding of human nature earned him the reputation of being one of the foremost diagnosticians of his time. As a scientist he was always an enemy of superficiality and a diligent searcher for the truth, never impatient or harsh with others, but unsparing of himself. He first began to attract attention through his observations on the effect of albumoses on the tuberculous and non-tuberculous organism. This was soon followed by his work with L. Krehl on fever. His reputation was enhanced by his leaning towards chemistry and physiology, and to this day his work on ulcer of the stomach done in 1897 remains fundamental."

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

THE SLUM CLEARANCE BILL.

ON Tuesday, July 1st, Standing Committee A of the House of Commons completed the consideration of the Housing (No. 2) Bill after a sitting of seven hours.

WHO IS TO MAKE THE REPRESENTATIONS?

On Clause 44 (provisions with respect to official representations),

Sir P. PILDITCH moved two amendments with the object of maintaining the law as it stands in regard to official representations made to local authorities. He said under the present law in the Act of 1925, whilst in all important matters such as clearances, big and important schemes and the like, the representation must be made by the medical officer of health in regard to smaller matters such as those dealing with the repair or closing of individual houses, it was open to a local authority to listen to the representations of other officers besides the medical officer of health. If the Bill passed as it stood the only person entitled to make official representations would be the medical officer of health. He agreed that in all important cases the medical officer was the proper person to make representations, but he did not think any case had been made out why in regard to all those small matters connected with separate houses and the like, the official representations should not be made by any other official of the authority, including the sanitary inspector. There was nothing in his amendments which proposed to alter the status of the medical officer of health as compared with that of the sanitary inspector. There was no desire to change the decision made in 1926 that the medical officer of health should be the superior officer in all cases.

MEDICAL OFFICER OR SANITARY INSPECTOR.

Mr. WOMERSLEY, who with Mr. BLINDELL had two amendments on the clause seeking the same object as the amendments moved by Sir P. Pilditch, said that he was putting his amendments forward on behalf of the Sanitary Officers' Association. As a member of a housing committee of a local authority he said he thought the sanitary inspector ought at any rate to be allowed to maintain his present status. He did not, however, suggest that the sanitary inspector should be given a greater status or a greater power to act over the head of the medical officer of health for the district. He looked on the medical officer of health as the superior officer, but at the same time he was satisfied from his own experience that it would be wise to allow the sanitary inspector to report direct to the health committee. He was satisfied that these men were capable of carrying out the duties which they would be asked to perform if these amendments were passed.

Dr. DAVIES said he was sorry to say that he was in direct opposition to both Sir P. Pilditch and Mr. Womersley, and he hoped the Minister of Health would not accept the amendment. He spoke as one who had some experience as a part-time medical officer of health. These part-time medical officers of health practically attended their office every day of the week except Sunday. The medical officer of health was responsible for the health of the district, including sanitation, and the sanitary inspector was directly under the control and orders of the medical officer of health. In a well-managed local authority the sanitary officials were very highly qualified men, who received the respect and support of their medical officers. But in his own experience the sanitary inspector always operated through him. If they made it possible for the sanitary inspector to make official representations to the local authority over the head of the medical officer of health, as he could do if these amendments were accepted, it would immediately cause a rift between the medical officer of health and the sanitary inspector. If the sanitary inspector had a definite opinion which did not meet with the approval of the medical officer of health, and acted over the medical officer's head, there would be divided responsibility, friction, and a very unhappy state of affairs. In local authorities and departments it was essential to have discipline. He did not desire to interfere with the status of the sanitary inspector in any way. After the medical officer of health he was the most important man in the health department of a local authority. But the medical officer of health was ultimately responsible, and if he could not trust his sanitary inspector it meant more work for him.

EXCLUSION OF THE SANITARY INSPECTOR.

Mr. McSHANE said he was very far from satisfied with the express exclusion of the sanitary inspector from the Bill, and he was not satisfied, considering this Bill in relation to the Mental Treatment Bill, with the further advance of medical officers. They were being very powerfully represented in that House in discussing measures which came before it. He denied any conflicting control whatever. No one would say that because the sanitary inspector was recognised in the Housing Act of 1925 it really caused any division of responsibility or conflict of control. He was not arguing on behalf of the Sanitary Inspectors' Association, as such, but because the sanitary inspector did the most valuable work he ought surely to be recognised as part of the official representation of the machine. The local authority had the ultimate responsibility, not any of its officials.

Mr. GREENWOOD (Minister of Health) said many of them were familiar with the procedure whereby particular interests—and he used that phrase in no invidious sense—did their best to exploit a situation in Parliament. He did not blame particular groups of people for trying to advance their interests in that way, but he must object to being drawn into this controversy between the sanitary inspector and the medical officer of health. His object in that Bill was not to improve the status of sanitary inspectors. He would like to see their status improved, but rightly or wrongly, their general objective was to secure a position as independent officers of a local authority. He contended that in a Housing Bill he should not be required to make a fundamental change in the structure of local government in this country. Such a request could only complicate the situation.

Sir P. PILDITCH: May I suggest that you are making the change? The amendments are designed to retain the law as it stands at the moment.

EXERCISE OF DEFAULT POWERS.

Mr. GREENWOOD said that was not the case. The real conflict was this. In this Bill the only change made in the position of the sanitary officer was with regard to default powers exercised in two kinds of local authorities only: rural district councils and metropolitan boroughs. He had to admit that that power was taken away from them. What was being asked for was an enlargement of their powers; in effect that the local authority should have an additional independent officer and be put in the position of having to decide between the two, with both appearing with equal authority before the council. He did not in any way burke this issue. He took the opportunity of ascertaining the considered views of the Association of Municipal Corporations in this matter. After all, both medical officers of health and sanitary officers were employees of local authorities, and the authorities were primarily concerned. In a letter which had been sent by the Association to the Ministry of Health, they stated their opinion that the medical officer, as head of the health staff, should only be mentioned. It was thought, the letter added, that grave difficulties might arise if a sanitary inspector were given a statutory right which would enable him to act independently of, and possibly in conflict with, the medical officer. In these circumstances the Association expressed the hope that he (the Minister) would not accept these amendments. He hoped that the Committee would support the deliberate view of the Association of Municipal Corporations.

Miss RATHBONE said that she thought that the Minister should leave the sanitary inspectors their powers in rural districts and metropolitan areas. If the case of the Minister had any strength at all it applied only to those authorities who had a first-class medical officer of health who was supreme. Rural areas where the sanitary inspector had exercised this kind of authority were just the areas where it was possible that a part-time medical officer, who was in general practice, might be unduly timid in making representations against the property of people who were his private patients. The sanitary inspector was always a full-time officer, and was not liable to that temptation.

Mr. HASLAM supported the view of the Minister of Health. Some hon. Members seemed to think that because a medical officer of health in a rural district was a part-time officer he was not very efficient. He protested against that point of view. No man was more fitted to give an opinion on housing conditions in rural areas than the medical officer whose whole life was spent in visiting patients in all conditions of life.

DISGRACEFUL CONDITIONS IN RURAL AREAS.

Mr. KINLEY said that those who had seen the disgraceful condition of some of the small property in rural areas thought that there was a case for the appointment of a full-time medical officer of health, or, if that was not possible, of a full-time sanitary inspector to cover the area.

Mr. GREENWOOD asked the Committee to put aside all talk about the extraordinarily efficient service of the sanitary inspectors compared with other services. They were all on much the same footing. Miss Rathbone had asked why they should not retain the powers which sanitary inspectors now enjoyed with regard to default in rural areas and metropolitan boroughs. What was the good of keeping these powers when this efficient service had never exercised them? These default powers had been a dead letter ever since they were placed on the Statute Book, and one of the purposes of this Bill was to simplify the default procedure and to make it more effective. There was no point in keeping machinery which had not worked and which was never likely to do so. It was now urged that under the 1925 Act sanitary inspectors had certain powers, but there was nothing in this Bill which interfered with that unless it was held that the expression "information in the possession of" the local authorities did not include the information received from sanitary inspectors. If it would help the Committee, however, he was willing to insert words in Clause 14 and in Clause 16 at a later stage to include officers of local authorities.

Sir P. PILDITCH said that so far as he was concerned, and he thought so far as Mr. Womersley was concerned, they realised that the Minister had done his best to meet them. It was a difficult point, but he thought that the right hon. gentleman's suggestion would meet their views in substance, though not perhaps so fully as they would desire.

The amendments were by leave withdrawn.

THE OVER-RIDING COUNTY COUNCIL.

Captain GUNSTON moved an amendment to leave out the word "county" in Subsection (1), and to insert instead the word "rural." He said that in Clause 44 they found a definition of the term "official representation" for the purposes of the other clauses of the Bill. Under this clause the medical officer of a local authority could make representations, but the clause went considerably further because it allowed the medical officer of the county council to over-ride the medical officer of an urban district council. He moved this amendment on behalf of the Urban District Councils' Association. That Association recognised that this was a good Bill as a whole, and that an effort was being made to secure amalgamation and coördination between various local authorities; but they protested against the attempt to draw an artificial distinction between a borough and an urban district. It was most undesirable that the discretion of the urban district council and the urban district medical officer should be interfered with by the county council, or the county medical officer. Those connected with urban government were not aware of any instances where urban councils had failed to carry out their duties under the Housing Acts, and he hoped that the Minister would show to the urban district councils more sympathetic consideration in this instance than he had shown in the past.

Dr. DAVIES said that under the proposal in the Bill the county medical officer could go into any district and if he found anything which did not meet with his approval, instead of seeing the district medical officer and asking him if something could not be done about it, he could simply go back to his headquarters and make a definite report to the county council that in a certain district such and such things had been neglected. This was bound to cause a terrible amount of friction and trouble between the county medical officer and the district medical officer, and to disturb the harmony which at the present time existed largely throughout the country.

Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that what they were doing in this clause was to re-enact the law as it had stood since 1890. All the happy relations described by Dr. Davies had grown up under the very clause which was being put back into this Bill. That, she thought, was a sufficient answer to the argument that the arrangement would cause friction and suspicion.

On a division the amendment was negatived by 22 votes to 8.

POWERS OF URBAN DISTRICTS.

Dr. DAVIES moved an amendment with the object of providing that the medical officer of health of an urban district should not be placed in a position of subjection compared with a borough medical officer. He said that this was not the time to draw invidious distinctions between large urban districts and small county boroughs.

Miss LAWRENCE said they were not drawing a new distinction, invidious or otherwise, but merely repeating what was in the Act of 1890. It was perfectly true that there were some urban districts that were as large as certain boroughs, but the bulk of the urban districts were very much smaller than the boroughs. She understood what the urban district councils were after: they desired to be boroughs. But the sensible thing to do was not to increase the powers of urban districts and assimilate them as closely as possible to those of boroughs; the sensible thing was to promote the great growing urban district populations to the full power of boroughs.

The amendment was negatived.

Captain GUNSTON moved an amendment to include urban districts having a population of 20,000 within the scope of the clause. He said he understood that the Parliamentary Secretary would accept this amendment.

Miss LAWRENCE accepted the amendment which was agreed to.

Clause 44, as amended was ordered to stand part of the Bill.

ALTERNATIVE ACCOMMODATION.

Major MILNER moved a new clause enabling a local authority to deal with cases where new houses had been provided, and it was desired to render alternative accommodation available for other persons in other houses belonging to the authority which were better suited to the requirements of the displaced persons. The clause also enabled the rents to be adjusted accordingly.

Mr. GREENWOOD, in accepting the clause, said it was largely an agreed one with the local authorities. It gave the local authorities a little power of interchange, and enabled them to mobilise all their housing resources in a better way. But there was nothing in the clause which required a local authority to build one house the less.

Lieut.-Colonel FREMANTLE said he was very grateful to the Minister for accepting this new clause.

The clause was read a second time and added to the Bill.

UNDERGROUND LIVING ROOMS.

Mr. HARRIS moved a new clause prohibiting the use of underground living rooms in London. He said that the clause had been considered at great length by the London County Council, and had been very carefully drafted.

Mr. GREENWOOD said this was not a clause the subject matter of which demanded different treatment as between London and the provinces. There might be a case for dealing with underground living rooms, but if they were to deal with them it must be done in a different way from this clause. If the committee felt that this was a matter which ought to be dealt with in the Bill he was prepared to consider on the report stage giving the principle general application.

Mr. HARRIS said he was satisfied with the undertaking, and would withdraw the clause.

The consideration of the Bill in committee was completed, and the measure was ordered to be reported to the House.

HOUSE OF COMMONS.

THURSDAY, JULY 3RD.

Factory Inspection in England.

Mr. GRAHAM WHITE asked the Home Secretary the number of new factories which had come under the factory inspectorate in the Midlands and the South, respectively, in the last five years.—Mr. CLYNES replied: The Midlands and the South are divided up for purposes of factory inspection into several divisions, and the following table will show the increase in the number of factories during the last five years in each of the divisions concerned:—

NUMBER OF REGISTERED FACTORIES IN MIDLAND, EASTERN, SOUTH-EASTERN, SOUTHERN, AND WESTERN DIVISIONS AT END OF 1924 AND 1929.

Division.	Number of Registered Factories.		
	At end of—		Increase.
	1924.	1929.	
Midland (*a*)	14,975	15,329	354
Eastern (*b*)	12,472	12,877	405
South-Eastern (*c*)	17,843	20,974	3,131
Southern (*d*)	16,900	19,421	2,521
Western (excluding Wales and Monmouthshire) (*e*)	8,492	9,066	574

(*a*) Counties of Warwick, Worcester, Stafford, and Shropshire.
(*b*) Counties of Nottingham, Leicester, Rutland, Lincoln, Norfolk, Cambridge, Huntingdon, Northampton, and Bedford; parts of the Counties of Buckingham, Hertford, and Suffolk.
(*c*) Counties of Essex, Kent, and Sussex; parts of the Counties of London, Surrey, and Suffolk.
(*d*) Counties of Middlesex, Berkshire, Oxford, Hampshire; parts of the Counties of London, Hertford, Buckingham, Surrey, and Dorset.
(*e*) Counties of Gloucester, Somerset, Wiltshire, Devon, and Cornwall; part of the County of Dorset.

Parents' Neglect of Child's Eyesight.

Mr. FREEMAN asked the President of the Board of Education whether his attention had been called to the case of Cyril Ford, aged 12, Raglan-road, Broad-street School, Bromley, Kent, who was forcibly given treatment to his eyes in May, 1930, by the representative of the school medical officer without the consent of his parents; and under what authority this treatment was given.—Sir C. TREVELYAN replied: I am informed that this boy was found at medical inspection to be suffering from a severe defect of the eyes and that he subsequently, with the full knowledge of his parents, attended the school clinic for a more thorough examination. Drops were put in the boy's eyes in the usual way to make the examination possible, but no treatment was given. The parents were then advised that the boy needed spectacles, but they refused to allow spectacles to be provided. In the last resort the National Society for the Prevention of Cruelty to Children initiated police-court proceedings, which resulted in the imposition of a fine for neglect.

Vivisection Experiments.

Mr. FREEMAN asked the Home Secretary whether he was now in a position to state the number of experiments conducted by vivisection during 1929; and, if so, how many were conducted on dogs and cats and how many when inspectors were present in each case.—Mr. CLYNES replied: The number of experiments performed during 1929 was 403,141; 2523 experiments were performed on dogs and cats under certificates E an EE. I presume the last part of the question is intended to refer to the presence of an Inspector at the actual operation in the case of those experiments which involve some operative procedure. If so, the answer is 157. The cases, however, in which the

experiment involves an operative procedure form only a very small proportion of the whole number, and the Inspectors, in the course of their visits, saw and examined many animals under experiment.

Osteopaths and Legal Recognition.

Mr. FREEMAN asked the Minister of Health whether it was his intention to introduce legislation to amend the Medical Act, 1858, so as to procure recognition and independent regulation of osteopathy, and give its properly qualified practitioners a legal status equivalent to that enjoyed by other recognised professions.—Mr. GREENWOOD replied: The answer is in the negative.

Committee on Sickness and Disablement Claims.

Dr. MORRIS-JONES asked the Minister of Health whether the committee of investigation into the causes of the increased sickness and disablement claims amongst insured persons had completed its deliberations.—Mr. GREENWOOD replied: No, Sir. The committee is still actively engaged in its investigation of the problem.

MONDAY, JULY 7TH.

Diphtheria and Antitoxin Treatment.

Mr. LLEWELLYN-JONES asked the Minister of Health whether he could furnish statistics for the decennial periods 1890–99, 1900–09, 1910–19, and 1920–29, indicating the average yearly number of notified cases of diphtheria in England and Wales, and the average yearly number of fatal cases of diphtheria during each period; and at what date approximately the use of the antitoxin treatment of diphtheria became general.—Mr. GREENWOOD replied: The following table gives such particulars as are available:—

	Average yearly number of	
	Cases notified (excluding non-civilians).	*Deaths* (including non-civilians).
1890–99	Not available	 7648
1900–09	,,	 6599
1910–19	*49,844	 4922
1920–29	54,484	 3486

* The average number for the period 1911–19. The first complete record of notifications of infectious diseases in England and Wales was for the year 1911.

As regards the second part of the question, I am advised that antitoxin was widely used by 1910 when local authorities were first empowered to supply it gratuitously.

War Pensioner's Medical Condition.

Mr. JOWETT asked the Minister of Pensions whether he would inquire into the case of F. C. Colman, ex-driver 21,729, Army Service Corps, discharged from the Army in July, 1918, suffering from duodenal ulcer, for which disability he was pensioned on the ground that his disability had been aggravated by war service, the pension being discontinued in November, 1921, consequent on a decision, after medical examination, that aggravation had passed away; and whether, having regard to the medical certificate recently submitted to him, which stated that F. C. Colman was still suffering from duodenal ulceration, although he was operated on three years ago for duodenal ulcer, he would reconsider his decision that aggravation had passed away.—Mr. F. O. ROBERTS replied: Mr. Colman's case has been fully reviewed, but the medical certificate referred to relates, not to the present time, but to the man's condition eight years ago and prior to the decision of the independent Pensions Appeal Tribunal in the case. In the circumstances, as I have already informed my right hon. friend, there are no grounds on which I should be justified in continuing further action.

Cost to Local Authorities Under New Housing Bill.

Dr. VERNON DAVIES asked the Minister of Health if he could give any estimate of the percentage of the cost per house to be borne by local authorities under the Housing (No. 2) Bill at the present level of building prices.—Miss SUSAN LAWRENCE replied: At the present level of average building prices a contribution of £3 15*s.* per house for 40 years is equivalent to rather more than 16 per cent. of the total cost per house.

TUESDAY, JULY 8TH.

Regulation of Hours in Offices and Commerce.

Sir KINGSLEY WOOD asked the Minister of Labour whether the position of salaried employees, and the convention for the regulation of their hours, had recently received her consideration in connexion with the Washington Convention; whether she had received any representations from any trade organisations in connexion therewith; whether the matter had been the subject of discussion at the recent International Labour Conference at Geneva; and whether any conclusions were reached at such conference.—Mr. LAWSON (Parliamentary Secretary to the Ministry of Labour) replied: The International Labour Conference on June 28th last adopted a draft convention concerning the regulation of hours of work in commerce and offices. Before the Conference met my right hon. friend received various representations from organisations interested in the subject.

The Calmette Treatment.

Mr. FREEMAN asked the Minister of Health the result of the inquiries of the representatives of the Medical Research Council into the death of 20 infants in Lübeck, Germany, following the Calmette prophylactic treatment.—Miss SUSAN LAWRENCE replied: No, Sir; but my right hon. friend understands that a report to the Medical Research Council on the subject of these inquiries is in preparation.

Subsidised and Non-subsidised Houses.

Mr. HORE-BELISHA asked the Minister of Health how many houses had been built during the 12 months ended June 25th, 1930, showing separately the number built with State assistance and private enterprise, respectively, and the corresponding figures for the previous 12 months.—Miss SUSAN LAWRENCE replied: Figures for houses built without subsidy of a rateable value not exceeding £78 (or £105 in the Metropolitan Police District) are only available in respect of the six months periods ending in March and September respectively. The figures for the 12 months ended in March are as follows:—

Year ended March 31st.	Private enterprise (A) with and (B) without State assistance.		Local authorities.	Total.
	(A)	(B)		
1929	64,740	49,069	55,723	169,532
1930	90,086	50,124	61,850	202,060

Miners and Silicosis.

Mr. JENKINS asked the Home Secretary the number of miners who had applied for compensation as a result of suffering from silicosis; what number had been paid compensation; and what number had been refused and the reasons for refusals.—Mr. CLYNES replied: The returns so far received show that there were 12 cases from coal-mines in 1929 in which compensation was paid for silicosis. I regret I cannot give the number of claims refused or reasons for the refusal.

GUY'S HOSPITAL.—The report for 1929 shows that the number of in-patients was 11,800; in 1924 it was 10,017. There was a decline of about 2 per cent. in the out-patients, but an increase in their attendances, which numbered 547,861. The dental department authorised 1417 dentures, much the highest record for any one year. There are 646 available beds, and the average stay of each patient has been reduced from 18¾ to 18 days, the most marked reduction being in the medical cases. The average weekly cost of each in-patient was £4 16*s.*, a fall of 4*s.* 5*d.*; out-patients cost 7*s.* 8*d.* Upon the year's expenditure of over £180,000 the adverse balance was £4535.

ROYAL VISITS TO HOSPITALS.—On Friday last week the Queen visited Queen Mary's Hospital for the East End, and received purses on behalf of the institution. The Duke of Gloucester, President of the hospital, presided at the ceremony. Her Majesty and the Duke afterwards visited some of the wards and the nurses' home.—On the previous day the Prince of Wales opened the new Monkwearmouth and Southwick Hospital, which has cost £100,000 and expressed his satisfaction that it is already paid for. There are about 100 beds, nearly double the accommodation of the old building, which is now almost entirely surrounded by factories.—On the same day Prince Arthur of Connaught opened the new general hospital at Margate, which has cost nearly £70,000. There are 80 beds and X ray and ophthalmic departments.—Recently Prince George opened the new men's ward of the Buchanan hospital at Hastings, and Princess Mary opened extensions, costing £14,500, to the Northwood, Pinner, and District Hospital. The enlargements increase the accommodation to 36 beds.

MEDICAL NEWS

University of Oxford.

At recent examinations the following candidates were successful:—

Medicine, Surgery, and Obstetrics.—A. D. C. Bell, W. D. T. Brunyate, J. H. Chitty, Amy C. E. Clarke, T. M. Davie, J. A. Eddy, A. J. Gibbs, Arthur Guirdham, R. D. Harding, Eugene Hardy, Frank Hawking, K. N. Irvine, W. H. McMenemy, W. E. S. Merrett, C. N. Milner, J. N. O'Reilly, T. R. Plummer, and Victoria M. Robinson.

Pathology.—Gerald Ashton, D. S. Bateman, J. H. B. Beal, R. A. Beaver, J. M. L. Burtenshaw, T. M. Davie, M. S. Good, I. H. Gosset, W. H. Greany, A. L. Jacobs, R. Kempthorne, R. C. MacKeith, R. M. Marshall, M. W. C. Oldfield, Robert Pakenham-Walsh, W. G. Rees, J. R. Robertson, W. L. Rusby, R. B. Scott, and J. H. C. White.

Forensic Medicine and Public Health.—A. D. C. Bell, I. M. Bell, A. J. Gibbs, H. C. Harley, Eugene Harvey, M. A. Hatt, Winifred Mercer, N. L. Rusby, and J. A. Scott.

Materia Medica.—A. D. C. Bell, I. M. Bell, Franklin Bicknell, R. H. Bolton, R. R. Bomford, Edward Braithwaite, Alan Carling, C. C. Cobb, H. G. N. Cooper, J. P. Dewsbery, M. S. Good, I. H. Gosset, A. J. Grace, C. E. Greenwood, C. F. Hamilton-Turner, Newton Heath, R. Kempthorne, Mervyn Mandelstan, P. J. W. Milligan, C. N. Milner, H. B. Morris, H. F. Moseley, Hugo Owen, Robert Pakenham-Walsh, J. E. G. Pearson, W. H. A. Picton, T. W. H. Porter, J. R. Robertson, G. E. Scott, F. M. Trefusis, F. G. Ward, J. H. C. White, and E. J. Williams.

The Theodore Williams scholarship in human anatomy has been awarded to Hugh Noel Davis (proxime accessit, Ralph Harrison Gardiner), and the Theodore Williams Scholarship in physiology to Thomas Meurig Williams.

University of Cambridge.

The governing body of Corpus Christi College have awarded to Dr. Reginald Hilton, assistant physician to St. Bartholomew's Hospital, the Copeman medal for research in medical and biological sciences. This medal was presented by Dr. S. Monckton Copeman, F.R.S., formerly a scholar of the college, and Mrs. Copeman. It was designed by Mr. T. H. Paget and struck by the Royal Mint. The present award is the first which has been made.

University of London.

At recent examinations the following candidates were successful:—

D.P.H.

Part I.—Raghunand Behari, Hilda M. P. Bond, Sarah Boyle, Annie C. Easterbrook, Lilian M. Griffiths, Chopra Harban Lal, Marjorie H. James, W. P. Jones, Samuel Lerner, Donald Magrath, R. J. Muzumdar, Edith A. Straker, Helen B. Sutherland, and Irene Yates.

THIRD EXAMINATION FOR B.D.S.

Ronald Lawton and W. M. Sinclair, King's College Hospital; and T. W. E. Pugh, Guy's Hospital.

Royal College of Surgeons of England.

On July 3rd three Fellows, retiring in rotation, were re-elected to the Council for the full period of eight years. The election was uncontested, and the result of the poll was as follows:—

	Votes.	Plumpers.
Sir Percy Sargent	521	43
Victor Bonney	514	52
Robert Pugh Rowlands	497	33

In all 629 Fellows voted, including 110 Fellows resident out of the United Kingdom; in addition 8 votes were found to be invalid.

University of Manchester.

At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR M.B. & CH.B.

W. W. Kay and A. L. Kenyon (with second-class honours), Roland Barnes, Allan Bigham, A. P. L. Blakely, Barbara E. Bleasdale, Edith M. Casasola, Winifred Dean, E. G. Elwell, Margaret M. Ferguson, C. D. Leflaive, G. M. Lendrum, J. C. Nicholson, G. J. Phillips, D. A. Richards, Edward Riley, Bernard Sandler, M. W. Smith, H. W. Thompson, Carl Verity, and N. S. Walls.

Part I., Forensic Medicine, Hygiene, &c.—M. M. Barritt, H. J. Beard, Margaret M. Bodoano, G. B. Carter, Nancy N. Carter, H. B. Craigie, P. M. Crowe, Jane Druker, Benjamin Dunkerly, K. P. Giles, Jessie Goldstone, William Hall, T. S. Heslop, Frank Livesey, Edith A. Longson, J. P. Longworth, Gerald Maizels, Simon Mills, Catherine O'Connor, Gerald Ramage, W. S. Ramsden, Constance M. Rostron, John Scully, J. C. Smith, G. G. E. Smyth, Alice Speight, Colin Starkie, Barnet Stone, Isaac Sutton, Kenneth Todd, and C. H. T. Wade.

D.P.M.

Nicholas Gebbie, H. C. Mulholland, and Benjamin Reid.

University of Birmingham.

On July 5th the following degrees and diploma were conferred.

M.B. & Ch.B.—A. C. Dawes, L. C. Rutter, and K. S. Williams (with second-class honours), E. D. Allen-Price, G. R. Bashford, R. V. S. Cooper, A. L. d'Abreu, Edwin Donovan, Alfred Elliott, Arthur Ingham, C. R. Kenchington, J. P. F. Lloyd, P. T. Merlin, R. L. Moiser, Harriet T. Stephens, T. C. Wilson, W. E. Wimberger, and Barbara E. Woodhead.

L.D.S.—S. D. Rosenberg.

University of Liverpool.

At recent examinations the following candidates were successful:—

M.D.

W. E. A. Burton, R. L. Corlett, Gwyneth Griffith, Muriel B. Hall, A. J. Hawe, E. W. Jones, and Edna E. Mawson.

M.B. AND CH.B. WITH HONOURS.

Class I.—G. W. Causey.

Class II.—Marjorie E. Birch and Honora J. Twomey.

FINAL EXAMINATION FOR M.B. & CH.B.

Regulations of 1923.—Part I.: M. L. Kaufman. Part II.: R. Fairhurst and R. Kossew. Part III.: A. L. Beresford, I. Kossew, and E. H. Williams.

Regulations of 1924.—Part A: F. J. Burke, H. T. Cank, W. J. Chisnall, L. M. Crooks, W. S. Diggle, H. G. Evans, I. Harris, J. H. Hughes, T. L. Hughes, E. R. Jammy, J. A. Jones, O. V. Jones, W. W. Laughland, T. E. Lennon, H. F. Loewenthal, A. J. Martinez, D. F. Morgan, P. B. Moroney, A. L. Potter, J. Sytner, R. H. Thewlis J. V. Tollington, Winifred Walls, A. R. Williams, and A. Wynroe. Part B.: L. G. Anderson, A. Blumfield, W. N. Chalmers, J. W. Cheetham, D. K. Collins, A. Curtis, W. Dodd, P. P. Fox, M. Glynn-Morris, D. O. Hughes, V. S. Hughes-Davies, A. T. Jones, R. P. Kemp, F. R. Kitchin, J. L. Mewton, J. Polonsky, W. J. Poole, M. Solomon, T. P. Twomey, and R. Wright.

D.P.H.

Part I.—A. Ashworth, Elizabeth M. Harding, and R. Krishna.

D.T.M.

K. C. McKenzie.

D.T.H.

G. R. Baxter, T. T. M. Chen, J. H. Dobbin, R. A. Heatley, G. B. McHutchison, E. S. R. Menon, C. K. Row, and T. Wilson.

Royal Medical Benevolent Fund.

During the first six months of this year the committee have voted £5208 in grants besides the usual payments to the annuitants. At the last meeting £646 was voted to 35 applicants. The following are examples of the cases helped:—

Widow, aged 43, of L.R.C.P. & S. Husband died in November, 1929, of tuberculosis contracted during the war. He gave up his town practice three years ago in order that he might work in the country. He was, however, unfit to do much work and such practice as was secured is not now saleable. The widow has been left with £150, no income, a boy 10 years old. Fund voted £26 and the committee have asked the Guild of the R.M.B.F. to assist the widow to find employment. The boy will be a candidate for Epsom. The Fund will keep in touch with the case, will ask other charities to assist, and will give further help from time to time.

M.R.C.S., aged 57. Has recently had a stroke and had to give up work. He is too ill to attend to his own affairs. The wife applied for help towards the education of the two children. Private income £200; it is not expected that the practice will sell for more than £650. Boy, aged 15, has one more year at school to finish, fees £120. Girl, aged 12, at school, fees reduced £30 a year. It is of the greatest importance that the boy should have his final year at school, after which he will be able to earn. Fund has agreed to pay £45 towards boy's school fees and will ask other charities to contribute towards the balance.

Daughter, aged 61, of M.R.C.S. Has been employed in an office, but has been seriously ill for many weeks. Sick pay of 12*s.* a week ceased on May 8th. She has now only £30 a year from another charity. Medical report stated that it would be a long time, if ever, before she could resume work. Voted £18 to be paid during the next six months when the case would be further considered. In the meanwhile medical comforts and service will be rendered by the Guild.

Subscriptions and donations should be sent to the hon. treasurer of the fund at 11, Chandos-street, London, W. 1.

Royal Medico-Psychological Association.

The eighty-ninth annual meeting of this association was held at Oxford from June 30th to July 4th. The business meeting was presided over by Dr. Nathan Raw, and the remaining sessions by his successor as president, Dr. T. Saxty Good, who delivered an address on the History of Littlemore Hospital. The membership, it was stated, has risen to 819.

Industrial Accidents and Diseases.

The sixth International Medical Congress on Industrial Accidents and Diseases will be held in Geneva during August, 1931. All information may be obtained from the Secretary of the British National Committee for this Congress, Mr. G. L. Perry, Industrial Welfare Society (Incorporated), 51, Palace-street, Westminster, S.W.1.

Fellowship of Medicine and Post-Graduate Medical Association.

On Monday, July 14th at 1.30 P.M., Mr. Mortimer Woolf will give a demonstration in the wards and out-patient department at Queen Mary's Hospital. On Tuesday, the 15th, at 2 P.M., Dr. G. Bourne will give a demonstration on children at the East London Hospital for Children. From July 21st to August 3rd a course in Diseases of Infants will be held at the Infants Hospital, Vincent-square. It will consist of lectures and demonstrations during the afternoons. In August there will be an all-day course at the Brompton Hospital, from August 11th to 16th, and an afternoon and early evening course at the All Saints' Hospital, Vauxhall Bridge-road, from the 5th to the 30th. The Fellowship also arranges for attendance at the clinical practice of some 50 London hospitals. Full particulars may be had from the Fellowship of Medicine at 1, Wimpole-street, London, W.1.

Paddington Medical Society.

At the first ordinary meeting of this society, held on July 8th at the Great Western Hotel, Dr. G. Sweitochowski being in the chair, a short address was given by Dr. G. E. Oates, medical officer of health for Paddington, on public health topics of general interest. Dr. Oates covered in his survey the diagnosis of small-pox, the supervision of rheumatism in children, and some questions of maternal and infantile mortality. On a motion by Dr. A. Baldie, vice-president, a section of the society was constituted for the purpose of examining and reporting in detail on the present working of the National Health Insurance Acts, with special relation to the proposed General Medical Service Scheme of the British Medical Association, and in particular on all questions affecting (*a*) organisation; (*b*) remuneration; (*c*) terms of service. The intention of the society is to have strong local consultative bodies to represent the views of practitioners in the borough. Dr. J. Cohen, hon. sec., reported on the present position of the London Public Medical Service. The next ordinary meeting will be held on August 12th.

Appointments

PEIRSON, T., M.B., Ch.B. Manch., has been appointed Deputy Medical Officer of Health for Plymouth.

Certifying Surgeons under the Factory and Workshop Acts: FREYER, T. D. W., L.R.C.P. Lond., M.R.C.S. (Abergavenny); ROBERTS, L. D., M.B., Ch.B. Birm. (Rugeley, Stafford).

Vacancies

For further information refer to the advertisement columns.

Aberdeen, City of, P. H. Dept.—Asst. M.O.H. £600–£750.
Aberdeen Royal Infirmary.—McRobert Lecturer in Malignant Disease. £800.
Aberystwyth Infirmary and Cardiganshire General Hospital.—H.S. £200.
All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley-road, N.W.—Hon. Surgical Registrar.
Barnsley, Beckett Hospital and Dispensary.—H.P. £200.
Barnstaple, North Devon Infirmary.—Res. M.O. At rate of £150.
Bath, Royal United Hospital.—H.P. and Asst. H.S. Each at rate of £120.
Bath, Somerset and Wilts. Central Children's Orthopædic Hospital, Combe Park.—H.S. At rate of £120.
Birmingham Children's Hospital.—H.S. At rate of £75.
Birmingham, Dudley Road Hospital.—Jun. Asst. M.O's. At rate of £200.
Birmingham, Midland Hospital, Easy Row.—H.S. £150.
Birmingham, Queen's Hospital.—H.S.'s to Special Depts. Each at rate of £70.
Birmingham, Selly Oak Hospital.—Surgeon. £700.
Blackburn Royal Infirmary.—Res. H.P. £175.
Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.
Bristol Royal Infirmary.—H.P.'s, H.S.'s, &c. Each at rate of £60. Also Cas. H.S. and Dental H.S. Each at rate of £80.
British Red Cross Society, Clinic for Rheumatism, Peto-place, Marylebone-road, N.W.—Hon Consulting Surgeons, &c. Also Med. Reg. £350.
Cambridge, Papworth Village Settlement.—H.P. At rate of £100.
Canterbury, Kent and Canterbury Hospital.—H.S. At rate of £125.
Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75. Also H.S.'s, H.P.'s, &c. Each at rate of £50.
Chesterfield and North Derbyshire Royal Hospital.—H.S.'s. At rate of £175.
Delhi, India, Lady Hardinge Medical College and Hospital.—Radiologist. Rs.750 p.m.
Doncaster Royal Infirmary.—Three H.S.'s, and One H.P. All at rate of £200.
East Ham Memorial Hospital, Shrewsbury-road, E.—H.P. Also H.S. to Special Depts., and Cas. O. At rate of £150 and £120 respectively.
Egyptian University Faculty of Medicine.—Prof. of Hygiene. £E.1500.
Evelina Hospital for Children, Southwark, S.E.—H.P. Also Cas. and Out-Patient O. Each at rate of £120.
Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Res. Surg. O. Also H.P. At rate of £175 and £135 respectively.
Halifax Royal Infirmary.—Third H.S. At rate of £125.
Harrogate Infirmary.—Jun. H.S.
Hong-Kong, Medical Department.—Secretary. £800.
Hospital for Sick Children, Great Ormond-street, W.C.—Med. Reg. and Pathologist. £300.
Huddersfield Royal Infirmary.—H.S. At rate of £150.
Hull Royal Infirmary.—Asst. H.P. Also Cas. H.S. Each at rate of £130.
Indian Medical Service.—Commissions.
Ipswich Borough Mental Hospital.—Med. Supt. £700.
Islington Dispensary, 303, Upper-street, N.—Temporary Asst. Res. M.O. £20 a month.
Kensington, Fulham and Chelsea General Hospital.—Res. Cas. M.O. At rate of £100.
Leamington Spa, Warneford General Hospital.—Res. H.P. £165.
Leeds Public Dispensary.—Jun. Res. M.O. £150.
Leicestershire County Council.—Asst. M.O.H. £650.
Leicester Royal Infirmary.—Cas. H.S. At rate of £125.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liverpool, David Lewis Northern Hospital, Clinical School.—Med. Tutor and Reg. Two Surg. Tutors and Regs. Each £175.
Liverpool Heart Hospital.—H.P. £52.
Liverpool, Hospital for Consumption and Diseases of the Chest, Mount Pleasant.—Asst. M.O. and Pathologist. £150.
Liverpool University.—Johnston Chair of Biochemistry.
Manchester Northern Hospital, Park-place, Cheetham Hill-road.—Sen. H.S., and Jun. H.S. £130 and £100 respectively.
Manchester, St. Mary's Hospitals.—Four H.S.'s. At rate of £50.
Manitoba University.—Asst. Professor of Anatomy. 3500 dollars.
Margate and District New General Hospital.—Res. M.O. £125.
Middlesbrough, North Ormesby Hospital.—H.P. £120.
Miller General Hospital, Greenwich-road, S.E.—Cas.O. £150.
National Hospital, Queen-square, W.C.—H.P. £150.
Newark General Hospital.—Res. H.S. At rate of £150.
Newcastle-upon-Tyne, Royal Victoria Infirmary.—Jun. Asst. for Path. Dept. £300.
Newport, Mon., Royal Gwent Hospital.—Hon. Radiologist.
North Middlesex Hospital, Silver-street, Edmonton, N.—Radiologist. £3 3s. per Session.
Norwich, Norfolk and Norwich Hospital.—H.S. £120.
Nottingham General Hospital.—H.S. At rate of £150.
Oldham Royal Infirmary.—Two H.S.'s to Special Departments. Each at rate of £175.
Princess Louise Kensington Hospital for Children, N. Kensington. H.S. At rate of £75.
Reading University.—Independent Lecturer in Agricultural Bacteriology. £400–£500.
Redhill, Royal Earlswood Institution.—Jun. Asst. M.O. At rate of £250.
Richmond, Surrey, Royal Hospital.—Jun. H.S. At rate of £100. Also Hon. Surgeons and Physicians, &c.
Rochdale Infirmary and Dispensary.—Jun. H.S. £175.
Rochester, St. Bartholomew's Hospital.—H.P. and Cas. H.S. Each at rate of £175.
Royal London Ophthalmic Hospital, City-road, E.C.—Two Out-Patient Officers. Each £100.
Royal Naval Medical Service.—Medical Officers.
Royal Northern Hospital, Holloway, N.—Res. Out-patient Cas.O. and Anæsthetist. At rate of £70.
Roxburgh, County of.—M.O.H. £1000.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. for Out-patient Department. £150.
Sheffield, Jessop Hospital for Women.—Registrar and Obstetrical Tutor. £500. Also Asst. H.S. At rate of £100.
Sheffield Royal Hospital.—H.S. to Ear, Nose and Throat Dept. Also Res. Anæsthetist. Each at rate of £80.
Sheffield Royal Infirmary.—Two H.S.'s. Also Ophth. H.S. Each at rate of £80.
Shrewsbury, Salop County Council.—Asst. M.O. £600.
Southampton, Free Eye Hospital.—H.S. £150.
St. John's Hospital, Lewisham, S.E.—Hon. Surgeon, also Res. M.O. £250.
Truro, Royal Cornwall Infirmary.—H.S. £170.
Warrington Infirmary and Dispensary.—Jun. H.S. £175.
West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Jun. H.P. At rate of £100.
Wigan Royal Infirmary.—H.S. At rate of £150.
Willesden General Hospital, N.W.—Res. H.S. and H.P. £110 and £100 respectively.
Winchester, Royal Hampshire County Hospital.—H.P. £150.
Wokingham, Berkshire, Pinewood Sanatorium.—2nd Asst. M.O. £550.
Wolverhampton Royal Hospital.—H.P. At rate of £150.
Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.
York County Hospital.—Res. Anæsthetist and Asst. H.S. £150.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Snaith (Yorkshire).

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the District of the Marylebone County Court (Circuit 43). Applications should reach the Private Secretary, Home Office, Whitehall, London, S.W.1, not later than July 26th.

NOTES, COMMENTS, AND ABSTRACTS

IMPROVEMENT OF POSTURE.

By M. F. Forrester-Brown, M.S., M.D. Lond.,
VISITING SURGEON TO THE CHILDREN'S ORTHOPÆDIC HOSPITAL, BATH.

Few people seem to realise how far extension and hyperextension of the spine are movements limited to the cervical and lumbar regions, and in which only the parts of the thoracic spine adjacent to these other regions participate. The importance of this fact is that when the normal kyphos of the thoracic spine with its apex at the seventh thoracic vertebra has been increased from any cause, it cannot be effectively reduced by voluntary hyperextension exercises of the whole spine, for the mobile cervical and lumbar regions absorb the whole stress. It is only when these two regions are locked in flexion, or put out of action by suspension, that a hyperextending force has any chance of acting on the centre of the thoracic kyphos.

Another aspect of spinal anatomy that often seems forgotten is that the abdominal cavity is absolutely dependent for its shape on the curves of of the spinal column; while conversely the muscles of the anterior abdominal wall are the anterior stays of the vertebral column, their tension being dependent on its curves and vice versa. Thus if the lumbar lordosis is reduced to a minimum and the abdominal muscles are taut, the abdominal cavity has an inverted pear-shape, which reduces any tendency of the heavy organs in its upper part (like the liver and stomach) to slip downwards; in this position its posterior wall in the loin slopes forwards and downwards, forming a supporting bed for the kidney. If the lordosis is increased, the posterior wall becomes vertical, and any sudden stress from above will much more easily dislocate a kidney. If simultaneously there is poor tone in the body muscles, so that the ribs slope down and the anterior abdominal wall bulges forward, then the pear-shape of the cavity is lost, and all the heavy organs sag downward. It is evident that an operation to suture up one or more of these organs is not a satisfactory or radical way of dealing with the condition. Conversely, lifting of the ribs and retraction of the anterior abdominal muscles reduce the forward pull on the spine and the lordosis, so that the vicious circle is broken at two points (Fig. 1).

Just as there are different types of horse, of which the Clydesdale and race-horse represent the extremes, so also there are different types of human machines, even in the same race. Some are built with heavy bones and short strong muscles and ligaments (Fig. 2, A); others with light bones, loose joints, and atonic muscles (Figs. 2, B and 3). These differences are often exaggerated by disease, for anything which lowers muscle tone in the slender type renders them visceroptotic, so that a vicious circle is produced, while repeated stress on the muscles of the heavy type is apt to induce fibrous changes which stiffen their joints still further. The two types are well represented by the John Bull and the Uncle Sam of the caricaturists. Dr. J. E. Goldthwait,[1] of Boston, has demonstrated by X ray examination that a number of the heavy "stocky" type have only four lumbar vertebræ, while some of the very "long-waisted" ones have six.

Owing to the attachments of the deep cervical fascia, when the chin is thrust forward and there is a cervical lordosis, the strands which pass down to the pericardium are relaxed, so that the heart can sag down and with it the central tendon of the diaphragm, which naturally impairs both circulation and respiration, another of the numerous drawbacks to the kypho-lordotic position of the spine.

[1] Jour. Orth. Surg., 1920, ii., No. 7.

The Pelvic Tilt.

The simplest countryman understands that one cannot put on the top storey of a house until one has built the ground-floor and foundations; yet medical men are constantly trying to alter the position of the upper bricks of the spinal column without adjusting the base on which they stand. In other words, no type of shoulder exercise will put the thoracic spine into a correct attitude until the lower limbs, pelvic girdle, and lumbar spine are successively put into the correct relationship to one another. An excessive tilt of the pelvic ring may be associated with different types of faulty balance above it, but the easy correct balance is practically impossible to attain until the pelvis has been tilted back the right amount by contraction of the glutei, pulling the sacrum down, and of the abdominal muscles, pulling the pubis up, and both together antagonising the powerful iliopsoas. It is probably impossible to over-correct the pelvic tilt by active exercises; on the other hand, when the muscles are relaxed by anæsthesia or by chronic illness and if the patient is kept recumbent on a hard surface—like an operating-table—without any support for the normal lumbar lordosis the lumbosacral and sacro-iliac joints are frequently strained, and become the source of chronic pain for a long time afterwards. A small cushion should therefore always be put under the lumbar region of a recumbent patient. Also, when the lithotomy position is used, care should be taken that the thighs are not flexed to an extreme degree so that the tension on the hamstrings pulls the lower end of the pelvis forward and strains the sacro-iliac joints.

Joints depend for their protection from constant strain, as distinguished from sudden jerks, on the tone of the muscles and not on the ligaments, which are merely a kind of outpost ready to resist surprise attacks momentarily and to call the main army of muscles to their aid. Now the sacro-iliac joints, though crossed by the fibrous origins of the glutei and spinal muscles, are not directly supported by any powerful muscle-group and yet are subject to the stress of the whole weight of the trunk and upper limbs. It is very important, therefore, that the body should be so balanced as to reduce the strain to a minimum, especially after the ligaments have been softened by pregnancy. Increase of the pelvic tilt especially if associated with a pendulous abdomen, will enormously increase the load on these joints, while in rheumatic subjects the strain may localise a rheumatic process; hence the tendency to symptoms in this region after middle age. Similar stresses on the lumbar and lumbo-sacral articulations are apt to be followed by inflammatory reactions in the posterior joints, which lie in intimate relationship with the roots of the nerves of the lumbar and sacral plexuses, so that the symptoms are often referred to the lower limbs although the seat of the trouble is in the back. Sciatica, in the sense of a true neuritis of the sciatic nerve, is rare, whereas sciatic pain referred from faults in the bones and joints of the lower part of the back is very common.

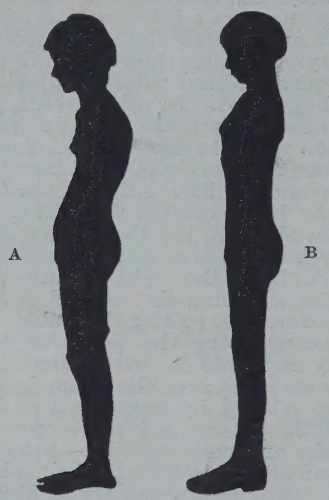
Muscle-Balance.

Joints are too often regarded as hinges, like those of a door, whereas they are living structures, completely under the control of a complex system of muscles, which are themselves balanced through an elaborate network of nerve centres. A "fatigued muscle" is really a fatigued nerve centre, and if the vitality of these centres is diminished by chronic toxæmia, or some other unfavourable general condition, it is not by any system of "exercises" that their function can be improved, but by doing away with the deleterious conditions, and meanwhile resting the centres as much as possible. This explains the value of recumbency in the treatment of postural faults due to malnutrition or chronic disease.

The effects of "exercises" in improving nerve control and muscle "tone" must not be confused with their effects in improving the circulation and the oxygenation of the blood. Thus, exercises directed to produce a series of deep inspirations and complete expirations have a beneficial effect on the whole body by increasing the oxygen content of the blood, emptying the abdominal veins by suction and so reducing the work of the heart, and also, by the swing of the diaphragm and of the abdominal muscles, massaging the liver and intestines (Fig. 4, A and B). All this is independent of the increased control of the trunk muscles that may be gained. Similarly, exercises may have a psychological value, even though they have no value in improving the balance of the spine directly.

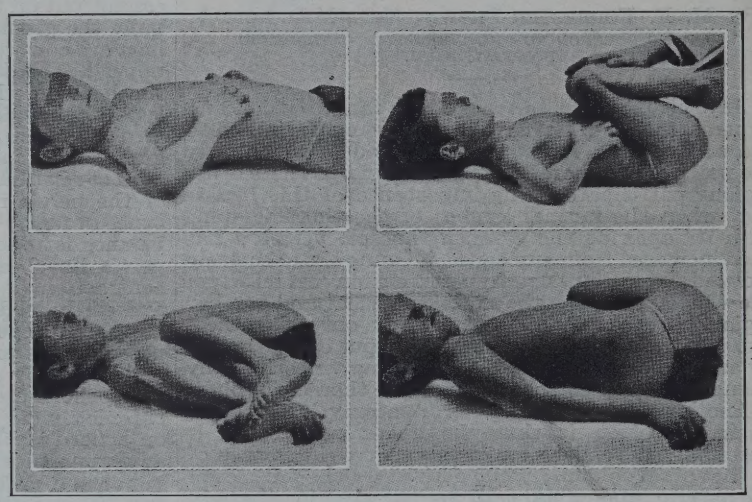
The nerve control of balance is chiefly maintained by a series of reflexes, which are outside the control of volition and which can only be modified indirectly. The sensory receptors for these reflexes are mainly in the eyes and labyrinth, and the reflexes are directed to maintaining the eyes horizontal. This brings me back to my previous contention that it is essential to have a correct attitude for the base of the spine, if the parts above are to assume some particular direction; for once the base is tilted in a certain axis, then the reflexes from the eyes and labyrinth will induce a series of compensatory curves which cannot be altered by any voluntary effort directed to them alone. This is very evident in cases of severe deformity of the spine due to tuberculosis, for in untreated cases the eyes are practically always found facing horizontally forwards, through the spontaneous production of large compensatory curves in all the rest of the spine. Such spontaneous curves often render the deformity very conspicuous, and a large part of the surgeon's art in the treatment of tuberculous spines consists in deliberately localising

FIG. 1.



(*a*) Faulty posture before treatment—rigid so that no improvement is possible at once. Note sagging at knees, prominent abdomen, hollow back, with thoracic kyphos above, dropped ribs, poking chin and hollow at back of neck.
(*b*) Same case after 3 months' treatment by Goldthwait's exercises and recumbency in an open-air hospital. Note straight knees, retracted abdomen, straight spine, expanded chest and back of neck well stretched. This is the position of attention, but even in the relaxed position the patient could not resume her old extreme slouch.

FIG. 4.

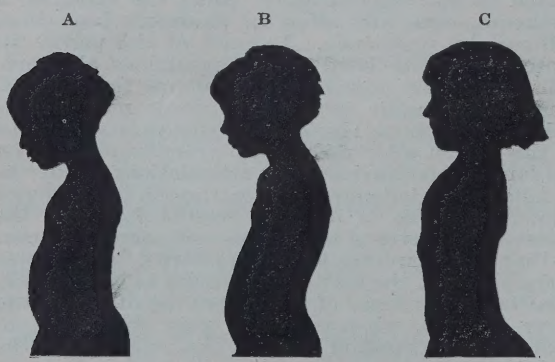


Physical exercises for children.

The *upper* photograph shows full respiration, assisted by knee flexion, for a young child; on the left: inspiration—ribs pulled wide by fingers; on the right: expiration—abdomen compressed by flexed thighs.

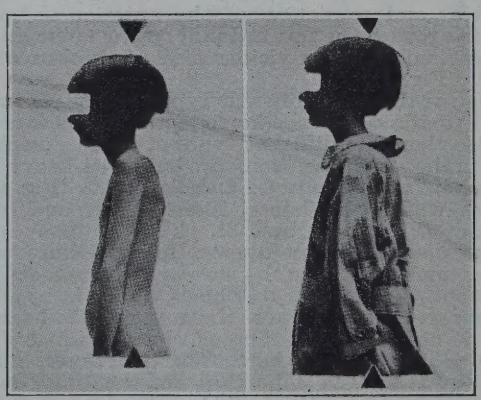
The *lower* photograph shows knee rolling exercises to increase abdominal tone. On the left the knees are seen drawn up into the right axilla while the chest is steadied by grasping the table—i.e., active twisting of the trunk. On the right the knees are seen rolled over into the left axilla, after which the lower limbs will be straightened out and the spine will be stretched.

FIG. 2.



(*a*) Boy of 4 years with extreme faulty posture: heavy type (John Bull in the adult).
(*b*) Girl of 5 years, similar posture; thin visceroptotic type (Uncle Sam in the adult).
(*c*) Girl of 5 years, healthy posture: medium type.

FIG. 3.



Faulty posture in the thin mobile type, easy to correct but hard to maintain. Undressed and dressed, showing how clothes mask the defect.

the compensatory curves in such a way that they shall be inconspicuous. It is rarely possible to prevent the collapse of some vertebral bodies, which is inevitably followed by the projection backward of the corresponding spinous processes. In the lumbar region, where a lordosis is normal, such a degree of kyphos merely renders the lumbar spine rather straight, a deformity not noticed by the lay eye. Moreover, in this region the position of the posterior articulations allows one vertebra to settle down vertically on to the one below, with no alteration in the angle. Such a settling-down is impossible in the mid-thoracic region, owing to the length and obliquity of the spinous processes, as well as to the arrangement of the posterior articulations. Therefore tuberculosis in the mid-thoracic region gives the most marked deformity, and is most difficult to mask by any form of treatment. Of course, if the patient with such a kyphos is allowed to walk at an early stage, there will be increase of the deformity, not only by further collapse of softened, tuberculous bodies but also by the action of the postural reflexes. Moreover, the erector spinæ in the thoracic region, besides being weakened by the toxins of the disease, has to work round a convexity, and is at a mechanical disadvantage in comparison with the same muscle acting across the concavity in the lumbar and cervical regions; the greater the kyphos the greater the mechanical disadvantage. In the upright position there is practically no apparatus which will counteract the deforming forces of these three factors.

Conclusions.

The practical conclusions of the above observations are:—

1. Increase of any one of the normal curves of the spine is associated automatically with increase of the other two, and in correcting them it is essential to begin with the lowest curve, so that the natural reflexes may assist instead of hindering the reduction of the other two.

2. Lumbar lordosis has a pernicious effect on the abdominal organs, kyphosis on the expansion of the lungs, and cervical lordosis on the heart and respiration.

3. All corrective exercises must aim at increased nerve control and balance, and defects of muscle-tone must be treated by a due proportion of rest, while the extensors of the spine cannot be usefully developed apart from the abdominal muscles (Fig. 4, C and D).

MEDICINA IN NUMMIS.

To the Editor of THE LANCET.

SIR,—The University of Vienna is in possession of one of the largest and most important collections of medical medals which was collected by the well-known research scholar Dr. Josef Brettauer of Trieste, who died in the year 1905. The collection, named the Brettauer Collection, after the donor, comprises some 7000 medals, among which there are artistic and historical works of great value of Renaissance, baroque, and modern art. This collection covers a wide field, and offers still unexhausted sources to the student of medical history. There are three chief groups. The first group concerns physicians of all times and nations, the second epidemics (especially plague, smallpox, cholera), famine, and want. The third group comprises, in many subdivisions, medals referring to healing gods and patrons of medicine, hospitals, and welfare institutions, medical corporations and congresses, nursing, ambulance, nearly all special branches of medicine and the medical auxiliary sciences, pharmacy and veterinary science, besides amulets, professional jetons, and satirical medals.

The control of this precious collection was recently transferred to the medal cabinet of the Art-History Museum. In accordance with the regulations of the foundation deed a small selection is exhibited for public inspection. The collection itself, which is in the exhibition room of the federal collection of medals, coins, and money-tokens, is open to all interested in this branch of science. Students of numismatics both here and in other countries are showing great interest in this unique collection, with highly satisfactory results.

The publication of a scientific catalogue of the collection, provided with the necessary photographs and drawings, &c., of medals of special historical importance is extremely desirable. As the cost of such a catalogue, which is estimated at least at 10,000 schilling (Austrian shillings), cannot be covered altogether by a donation of the Austrian Government, the undersigned apply, on behalf of the committee of the Brettauer Collection, to all friends of science and art, and especially to medical historians and numismatists, as well as to medical faculties, medical associations and societies, both here and abroad, to be good enough to send their contributions to the office of the rector of the Vienna University. A list of donors will be published in an appendix to the catalogue.

On behalf of the committee of the Dr. Josef Brettauer Collection of Coins,

Prof. Dr. WENZEL GLEISPACH,
Rector of the Vienna University.

Prof. Dr. MAX NEUBURGER, President of the Institute of Medical History.
Prof. Dr. AUGUST LOEHR, Director of the Collection of Medals, Coins and Money-Tokens in the Art-History Museum.

STUDENTS' WORK IN THE VACATIONS.

IN increasing numbers each summer English undergraduates are trying to find paid work to occupy their long vacation. There is in this country no tradition in favour of such employment, and now that many students from the middle and working classes find it necessary that they should make some contribution to the family exchequer, the difficulties in the way of their obtaining temporary paid posts are almost insuperable. Writing from the National Union of Students (3, Endsleigh-street, London, W.C.1), Lord Derby suggests that these difficulties are partly due to the reluctance of employers to employ undergraduates in a way with which the last generation was not familiar. He believes that, if more were known of the students seeking such employment, it would be found that there are many temporary posts which they could suitably occupy. In the present summer many hundreds of students are looking for vacation work, and the Union is in a position to introduce suitable applicants to any employer who will apply to the secretary.

EFFECTS OF CASTOR OIL SOAP ON BACTERIA.

THE discovery of W. P. Larson that certain virulent strains of bacteria, when immersed in solutions of sodium ricinoleate, become avirulent was attributed by him to a surface tension effect. This theory was found, however, to be unsatisfactory since other soaps which are effective in lowering surface tension are much less so in detoxifying toxins. Dr. R. R. Spencer,[1] of the U.S. Public Health Service, now publishes a series of observations on the clearing of certain bacterial suspensions by the addition of solutions of sodium ricinoleate. The effect of this solution varies widely according to the species of bacteria. *B. tularense* in suspension of turbidity 250 is cleared immediately with solutions of castor oil soap as low as 1 : 800. No other bacterial suspension is cleared by this low dilution—the distinction is, indeed, so marked that Spencer suggests this technique as a new method for identifying *B. tularense*. Other bacteria are cleared in higher dilutions, *B. pestis*, for example, at 1 : 200 and *Spirillum choleræ* at 1 : 100. Whenever there was a complete disappearance of visible turbidity a marked increase in viscosity occurred.

More remarkable, perhaps, is the increase in turbidity noted in suspensions of *B. columbense* and *B. niger* at certain definite (and in each case specific) dilutions of the sodium ricinoleate. This phenomenon is no more easy to explain than is the fact that many bacteria do not seem to be affected at all.

THE CALDECOTT COMMUNITY.

THE Caldecott community is a school in Hertfordshire where children, chiefly from the slums, are given the advantages of a country boarding-school life. How much they gain from it is fully evident only to those who visit the school itself; but some idea of the success of the experiment can be gained by seeing the plays annually performed by the children. This year they will again have a London evening, and judging by previous experience, it should be well worth going to the Rudolf Steiner Hall on July 17th to attend it. The play is called The Son of Jochebed, and is taken from Edmund Fleg's "La Vie de Moïse." In the words of the preliminary leaflet:—

"You will not see Moses in the Bulrushes, but you will see him strangle the Taskmaster, and the Burning Bush will really burn and not be consumed, to music by Schumann (this is a very difficult part); and, of course, you will see the frogs and the death of the first-born, and the ripples of the Red Sea as the Children of Israel cross it: this will be difficult too, for the sea will move to one rhythm while the Children pass through it to another, and we have to keep our heads as we are sure the Israelites had to: and, of course, you will see Pharaoh and his chariots drowned as well—we couldn't leave that out, however difficult."

Tickets may be had from Miss Potter at the Caldecott Community, Goff's Oak, Cheshunt, and nobody who buys one is likely to regret it.

A MOTOR-CYCLE ACCIDENT.

Mr. Arthur S. Nicoll (25, Ringstead-road, Catford, S.E.6) informs us that he is anxious to get into touch with a medical man who witnessed an accident to a motor-cyclist and pillion-rider, "who was run down by a car on the way to Hastings on Sunday, June 22nd, 12.30 noon." The doctor gave his card at the time, but it has been lost.

ALLERGIC INSULIN REACTIONS.

WHATEVER the chemical nature of insulin may prove to be, it is at present impossible to separate the hormone from the tissue proteins of the animal from which it is prepared, and it is therefore not surprising that its use should be occasionally attended by those local and general reactions which are apt to follow the hypodermic injection of foreign protein. Indeed, the surprising fact is that such anaphylactic reactions are not more often encountered. Local reactions, consisting of an itching area of erythema round the site of injection, were commonly seen during the use of the earlier preparations of insulin, which were rich in protein, and are still met with occasionally. They can usually be avoided by changing the brand of insulin. General reactions of the anaphylactic type are fortunately rarer still, but an almost fatal case described by J. R. Williams[1] emphasises their importance.

The patient, a diabetic boy of 12, had been having insulin injections for over two years, when he suddenly became ill with severe abdominal pain and vomiting. He was unable to retain any food and rapidly developed a ketosis, which could not be controlled by increased doses of insulin. Eventually, when the child was moribund the possibility of an allergic reaction occurred to the author, and on changing the brand of insulin, which was one prepared from the pancreas of the pig, for one made from beef pancreas, complete recovery occurred within 48 hours.

The importance of this case lies in the fact that such a train of symptoms, abdominal pain and vomiting, followed by ketosis, is so typical of early diabetic coma that the clinician can hardly be blamed for not suspecting the true state of affairs. A certain proportion of cases of diabetic coma do not respond to insulin treatment, and it is well worth bearing in mind the possibility of an anaphylactic reaction to the insulin in such circumstances. Certainly no harm can be caused by trying a different preparation of insulin. As Dr. Williams suggests, it would be helpful if manufacturers indicated on the package the animal source of their extract.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, July 14th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.
TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Ear, Nose and Throat Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.
THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear, Clinics. Operations.
FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M., Medical, Surgical, and Children's Diseases Clinics. Operations.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

MONDAY, July 14th, to SATURDAY, July 19th.—QUEEN MARY'S HOSPITAL, Stratford, E., Mond., 1.30 P.M., Demonstrations in Wards and O.P. Dept. by Mr. Mortimer Woolf. No fee.—EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E., Tues., Demonstrations in Diseases of Children at 2.0 P.M., by Dr. G. Bourne. No fee. Further particulars from the Fellowship of Medicine.

MENTAL HOSPITALS ASSOCIATION, 5, Church-passage, Guildhall, E.C.

WEDNESDAY, July 16th.—11 A.M., Annual Meeting at Guildhall, London, E.C.

Births, Marriages, and Deaths

BIRTHS.

AINSCOW.—On June 23rd, the wife of Dr. J. Arthur Ainscow, Hagley-road, Birmingham, of a son.
BARNARD.—On June 28th, at Aboyne, Sidcup, the wife of Dr. J. M. Barnard, of a son.
BRIDGES.—On July 1st, at "Hutton," Pampisford-road, Purley, wife of Major R. F. Bridges, R.A.M.C., of a daughter.

DEATHS.

CONAN DOYLE.—On July 7th, at Windlesham, Crowborough, Sir Arthur Conan Doyle, M.D., LL.D., in his 72nd year.
FALKNER.—On June 28th, suddenly, from heart failure, Henry George Falkner, O.B.E., L.R.C.P. & S.I., of Park-crescent, W.
GERVIS.—On June 30th, at Shepway, Seaford, Sussex, Charles Berkeley Gervis, M.D., M.R.C.S., L.R.C.P., aged 54.
TAYLOR.—On July 1st, at West Heath-drive, Golders Green, Frank Edward Taylor, M.A., M.D., M.Sc., M.R.C.P., F.R.C.S.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

PLYMOUTH CITY COUNCIL: LOAN FOR PURCHASE OF RADIUM.—The Council has decided to borrow £24,000 for the purchase of radium, the Ministry of Health having promised to consider the proposal in the same way as every other application for a loan. The health committees of Devon and Cornwall will participate in the scheme. In 1928 there were 340, and in 1929 297 deaths in Plymouth from cancer. It is expected that 20 beds will be set aside, one half for the counties of Devon and Cornwall, and the other half for Plymouth.

RECOVERY OF HOSPITAL EXPENSES.—Under Section 16 of the Local Government Act, 1929, local authorities are empowered to recover the cost of maintenance of patients in hospitals, maternity homes, and such like institutions, either from the patients themselves or from those legally liable to maintain them, exception made of cases of infectious disease and of cases where the authority is satisfied that exemption ought to be granted in respect of part or all of the cost. Plymouth has now drawn up a comprehensive scale of charges and exemptions based upon income and the number of the family. The exemptions range from incomes of £104 to £250—one in family in the first instance and eight in the last. Liability to the full charge begins at £208 (one in family) and goes up to £400 (eight in family). There are, however, three intermediate scales fixing the proportion of the cost to be recovered at 25, 50, and 75 per cent., according to income.

ADDRESSES AND ORIGINAL ARTICLES

NEUROHYPOPHYSIAL MECHANISMS FROM A CLINICAL STANDPOINT.*

By Harvey Cushing, M.D., C.B., F.R.C.S. (Hon.),
PROFESSOR OF SURGERY, HARVARD UNIVERSITY.

Joseph Lister, in whose name this triennial lectureship has been established, was a practitioner of surgery and at the same time a savant—or as near an approach to one as the definition of the term can permit a surgeon to be. It is a rare combination, for the two careers are well-nigh incompatible, one or the other of them, by those capable of either, usually having to be sacrificed. Science demands of the true savant a devotion which admits of no sharing; wholly unconcerned with the application of theory, he consecrates himself to a form of intellectual activity which brooks little or no interruption. The surgeon's time, on the other hand, lies open to the behest of afflicted persons who in mounting numbers seek his aid; and if he is at all benevolent, they cannot be refused. Seldom, therefore, can the diverging paths be long trodden together; the straddle becomes too great.

Those fully qualified and who have essayed to lead the double life have usually found themselves burdened beyond sufferance. In spite of his unlimited capacity and passion for work, this, in our own time, was the experience, if I mistake not, of that man of superhuman standards, Victor Horsley. John Hunter, who also kept up the divided allegiance throughout a life of unparalleled industry, was constantly harassed by obligations to his patients though they provided the guineas needed for his researches. Others like James Paget, who once said: "There is nothing that a man may not be at the same time that he is scientific," have taken the Vesalian course ultimately, after a brave start, to abandon their scientific pursuits altogether. Lister alone of those whose names come readily to mind had the placid disposition which enabled him to carry the double burden with equaminity. The major problem, to be sure, which he set himself to solve was born from the urge of practical necessity, but this was no less true of many of Pasteur's more important later researches. Each none the less remained a savant for all that.

To invoke these great names within the walls of this College merely serves to emphasise that most surgeons become increasingly involved in the snare of their practical work, the worries and responsibilities of which allow neither leisure nor that freedom of thought necessary for productive research. The time comes when most of them at best merely provide opportunity, stimulus, and possibly ideas and material for younger people to work upon; and yet the high regard in which science is held in these halls is shown by the fact that from Richard Owen to Arthur Keith a true savant has been Conservator of the great museum in which the memorials and traditions of Hunter's scientific labours survive.

What personal contributions, therefore, surgeons in their later years are likely to make to the store of scientific knowledge rarely causes any great stir. So what I shall have to say in this Lister lecture, on a subject which from small beginnings has grown beyond what any one person can readily compass, has mostly to do with the clinical interpretation of the recent discoveries made by others with some few of whom I have chanced to come into close working contact. And should Lister with Hunter and Paget and Horsley happen to look down from the spirit-world upon this gathering, my topic in spite of its modern aspects and terminology will not be wholly foreign to them. Hunter was deeply interested in the factors underlying growth in the abstract, Paget in the pathology of tumours, Horsley in the function of the ductless glands, and Lister, by teaching us how to eliminate wound infection, opened both in clinic and laboratory the innermost recesses of the living body to the surgeon's inspection. Had it not been for Lister, surgery would still be mainly "external" rather than largely "internal" as it has become, and we would have known, probably, little more about the region of which I shall speak than was known to Galen, to André Vésale, and to Thomas Willis.

Primitive Views of the Pituita.

Nature saw fit to enclose the central nervous system in a bony case lined by a tough, protecting membrane, and within this case she concealed a tiny organ which lies enveloped by an additional bony capsule and membrane like the nugget in the innermost of a series of Chinese boxes. No other single structure in the body is so doubly protected, so centrally placed, so well hidden. Her acts being purposeful, she must have had abundant reason for this, and man's prying curiosity impels him to ask what they were. But we may as well go back to the beginning.

When anatomists first undertook roughly to describe the brain, they were so baffled by the complexities of the region overlying the sella turcica that the best Galen, the greatest of them, could do was to call it "the seine-like net," and as he thought it an astounding structure those who came, long afterward, to put him into Latin used the term *rete mirabile* rather than the plain *plexus retiformis*. So as the "wonderful net" it continued vaguely to be described until, in the arterial plate of his *Six Tables*, Vésale first essayed to give a picture of it—*Rete mirabile, in quo vitalis spiritus ad animalem preparatur*. This figure was considerably altered when the *Fabrica* came to be published at which time drawings to show the mechanism of pituitary distillation were subjoined; but it was not until well on in the seventeenth century that Willis began to untangle the net by describing the vascular "circle," both arterial and venous, which surrounds it. Of the functional importance of the region Galen had no doubt, and we need not smile with complacence at the idea of its being a filter or trap whence the slime or pituita, the waste product of the transformation in the cerebral ventricles of vital into animal spirits, found its way into the nose and pharynx.

Willis, to be sure, found this explanation untenable, particularly since Schneider before him had demonstrated that pituita or phlegm was secreted by the nasal mucous membranes themselves. But could he have known, what in more recent times comparative zoology and embryology were to teach us, that in ascidian larvæ the ventricle and primitive mouth are in permanent communication, that the hypophysial homologue in amphioxus is a ciliated pit with an external secretion of slime, and that a demonstrable duct actually exists in the embryonic stage of all vertebrates, it would have lent strong support to the

* The basis of the Lister Memorial Lecture delivered, with illustrations, at the Royal College of Surgeons on July 9th, 1930.

Galenic doctrine. And likely enough, one or all of these great men may have encountered examples of cerebro-spinal rhinorrhœa still further to mislead them and confuse the issue.

We may well look charitably upon this ancient belief that the infundibular funnel and the subjacent gland was a mechanism of external secretion, for we are no less puzzled to-day to know what happens at least to the posterior "pituita," it being now the fashion to believe that it passes in the reverse direction—namely, up the infundibular stalk toward the tuber and ventricle; and in all certainty the recently discovered anterior pituitary hormone of sex has much to do with our vitality and animal spirits though no longer brewed in the ventricular cavities.

In his ample discussion three centuries ago of the functions of the *Rete*, of which he had made a comparative study on all available animal species, Willis stated:—

> "The ramification of the carotids into a reticulated plexus shows . . . . that the blood . . . . before it is let into the cerebrum takes some part of the superfluous serum of the pituitary gland and instils another part into the various hoots to be led back toward the heart."

There lies in this statement the kernel of the modern conception of an internal secretion, but the idea was stillborn, and though Harvey by this time had shown what might be learned concerning function by putting things to the test of well-devised experiments, the *Rete* and the gland it covered were well out of experimental reach. And not only out of reach, they went practically out of mind after comparative anatomy finally made clear that in higher animals traces might be found of structures that in lower forms had once been of functional importance. So in our ignorance, the pituitary glandule, newly named (1778) the hypophysis cerebri, was conveniently brushed aside as being of the limbo of vestigial relics.

Humours and Hormones.

Advances in scientific knowledge are based on speculative hypotheses, and the grain of truth they may contain is only established or disproved after disappointment and toil immeasurable. Out of Aristotle's theory of matter with its four fundamental substances—air, water, fire, and earth—grew the conception of the four humours—phlegm, blood, yellow bile, and black bile—over which medicine philosophised so long that our very speech has become permeated thereby. Our temperaments to this day are phlegmatic or sanguine, choleric or melancholy, and are likely so to remain, however much we may talk and write in modern hyper- and hypo-hormonic terms.

All this is intertwined with the age-long observations on the blood which the practice of venesection, both in illness and health, abundantly provided for study. In the formation of the clot the blood (*sanguinis*) and black bile were its solidified portion, the serum was yellow bile, and the supernatant "buffy coat" (*crusta sanguinis*) represented the phlegma on the thickness and character of which the diagnosis of disease largely rested. No observation in the whole history of medicine has played so important a rôle as this phenomenon of clotting which served for two thousand years as the basis of humoral pathology; and the dyscrasias and diatheses of our more immediate predecessors are but the rose by another name.

There came a time, to be sure, when attention was focused (1761) by the *De sedibus* of Morgagni on the solid organs as the seat and cause of disease; but the importance of the body fluids could not long be kept in the background, and soon Théophile de Bordeu, a practitioner of Paris, propounded the view (1776) that each gland and organ provides some specific substance or secretion which, passing into the blood, regulates the physiological integration of the body—an idea that supposedly influenced Bichat in ascribing (1802) a specific vital property to each classifiable tissue.

Not, however, until Claude Bernard's brilliant studies of hepatic glycogen (1853), which supplied the conception of an internal as opposed to an external organic secretion, was there struck what we recognise as a truly modern note in all these speculations. So Brown-Séquard, among others, became imbued with the idea (1856) to which he tenaciously adhered throughout his long life, that each cell secretes on its own account certain products or special ferments which influence all other cells of the body by a mechanism other than the nervous system. From this conception, that something in the nature of an internal secretion is taken up from every tissue by the venous blood, the way was blazed for Bayliss and Starling whose chemical messengers or hormones (1902) have given a new impetus to the experimental studies of the ductless glands, brought back animal extracts into the pharmacopœia, and provided us with a wholly new kind of humoral pathology.

We have, to be sure, more hormones than Galen had humours, but they serve much the same speculative purpose. It was pituitary body of old that secreted the phlegm which was cold and humid and when predominant caused constitutional indolence or apathy. In Galenic terms we could well enough explain the placid temperament of a patient with a chromophobe adenoma as one who is dry and sluggish from retention of pituita in the phlegmatic glandule.

To one Galen in the second century there are uncountable inquisitors of biological phenomena in the twentieth, however Lilliputian their efforts may be in comparison. So it was inevitable that some searcher or re-researcher should again find signs of functional activity in this nigh forgotten gland. It came about, I should say, through Ludwig's invention of the kymographion, by which, on countless miles of smoked paper during experimental procedures, changes in blood pressure, among other things, have since been graphically traced. And when a pressor substance was thus shown by Schafer to be present (1894) in extracts of the pituitary body, albeit in its posterior portion alone (1898), here was indubitable evidence that the structure was at least not so vestigial as to be functionally extinct.

But this disclosure, important though it was, was not what first drew renewed attention to the neglected organ. Our knowledge of the processes of disease almost invariably starts with the description by someone of a clinical syndrome which others quickly recognise, and only then does the labour of running it down to its seat and cause really begin. So from clinicians such as Addison and Gull, and Graves and Basedow, and Marie, to mention but a few of them, came our first recognition of the group of maladies we have learned to associate with disorders of the ductless glands. And later when Lister had made it possible to extirpate with safety some of these organs that happened to be causing mechanical trouble through tumefaction, the symptomatic effects of glandular deprivation began to be made apparent.

Organs more readily accessible to attack were naturally enough those to be first subjected to this form of inadvertent surgical experimentation, and what part Kocher and Horsley and Halsted, all belonging to this College, I may add, came to play in forwarding our knowledge of goitre and in safeguarding its operative treatment I need scarcely recall. Nature gives up her secrets grudgingly

and in this instance she had virtually to be taken by the throat before the independent rôle played by Sandström's glandules was disclosed, for these inconspicuous bodies served to obscure the actual consequences of thyroid extirpations until Gley finally (1891) showed the reason why. All told, this practical conquest of goitre represents one of the most illuminating achievements of modern medicine, for out of it grew the belief that for each of the ductless glands we might some day expect to recognise a clinical syndrome due to oversecretion and an opposing syndrome due to insufficiency for which treatment by substitution might offer promise of cure.

Thus a conjecture long held by many was crystallised into the conviction that has given birth to the new and special subject of endocrinology which is sweeping aside many of our established views of disease in a tidal wave as destructive as that which swept over medicine at the end of the last century upon the discovery of the bacterial origin of the infectious diseases.

The Anterior-Pituitary Syndromes.

In Volume VII. of Murray's "New English Dictionary on Historical Principles" issued in 1909, the pituitary gland is thus defined: "a small bilobed body of unknown function attached to the infundibulum at the base of the brain; originally supposed to secrete the mucus of the nose." Since learned men were consulted in the preparation of this great lexicon it may be gathered that our knowledge of the activities of the structure in question has been gleaned in the past two decades. But some 20 years before that, what served first to reawaken interest in the region encircled by the Willisian vessels was the ultimate disclosure that the strange malady, which Marie had picturesquely but inadequately named acromegaly, was usually accompanied by an hypophysial tumour. What is more, pathological gigantism was soon recognised as a corresponding condition which differed merely in that it began at an earlier stage of life. One can imagine how excited John Hunter would have been at this discovery could it have come in his day and generation. His employment of madder-feeding (1756) in studying the growth of bone may be recalled—a method recently revived (1930) by Handelsman and Gordon in estimating the response of osseous tissues to the pituitary hormone of growth. Indeed, had not Hunter's passion as a collector of specimens momentarily exceeded his thirst for knowledge when he came to prepare the skeleton of the Irish Giant, he could scarcely have overlooked the hypertrophic gland with its enlarged fossa, the presence of which was not detected until Arthur Keith's inquisitive finger was put into it more than a century later.

So it was the tumefied gland that finally betrayed the organic locus of Marie's disorder, and this tumour, in some inexplicable way, was evidently associated with a tendency to hypertrophic changes in the skeleton. But we were far from being as yet on solid ground even in regard to this single and striking factor of growth. Though the difficulties of solving the problem seemed nigh insurmountable, they one by one have been largely overcome by the disclosures with which all are now familiar. It was first learned that extirpation of the gland in young animals checks their growth, a negative indication that acromegaly must be due to glandular overaction rather than to diminished or faulty activity. It meanwhile had become clear from occasional post-mortem studies that the tumour in acromegaly was an adenoma, and the more recent examination of surgical specimens has taught us that it is invariably composed of the acidophilic elements of the anterior hypophysis. And finally came the crowning achievement by Evans and Long who in 1921 produced experimental gigantism in the rat by repeated parenteral injections of saline emulsions of fresh bovine anterior lobe tissue.

All this seems simple in the telling. Results get recorded, not the slow and painful process beset with discouragements by which they are attained. One of the chief sources of confusion lay in the disconcerting fact that, after Rontgen's discovery had laid bare the silhouette of the skull to our direct inspection, many patients with outspoken acromegaly were found to have an unenlarged pituitary fossa; and still more surprising, it was soon found that a tumour-expanded sella without signs of acromegaly was far more common than with it. Out of this it slowly dawned upon clinicians that pituitary tumours of the latter kind had an accompanying symptomatology, once it was pointed out, as characteristic and definitely recognisable as that of acromegaly.

Attention was first drawn to this peculiar combination of symptoms by ophthalmologists and by gynæcologists. Women with unaccountable amenorrhœa not infrequently complained of disturbances of sight, and when their eyes came to be examined indications of pressure against the optic chiasm were often disclosed. Then, as time went on, cases of this sort began routinely to be subjected to rontgenological studies, and the expanded pituitary fossa with which we are now familiar was the usual finding. But these conditions were not limited to women. Men were as likely to be similarly afflicted, and though in the male there is no periodicity of function to be so strikingly interrupted, it was nevertheless clear that entirely comparable disturbances in the attributes of sex were present in them as well.

How the surgeon has come to be drawn into all this is simply explained. The problem at the beginning was purely a mechanical one, similar to that which led to the first operations for goitre. When the enlarged thyroid so compressed the trachea as to produce dyspnœa, surgical intervention was called for, whatsoever the hazard; the pituitary "goitre" similarly affected the optic chiasm by pressure, and unless this was relieved blindness might ensue. And so when ways of operating upon these more common hypophysial tumours came to be devised and surgeons with increasing confidence began to attack them and to provide tissues for study, they were found to be adenomas of an altogether different kind from those which accompany acromegaly.

THE ADENOMAS IN GENERAL.

Experimentation is by no means confined to the laboratory. The putting of ideas to the test with the elimination of error by trial is also necessarily the practice of the clinic. This is well exemplified in the case of the adenomas of the secretory organs, once regarded merely as curiosities of morbid anatomy but now shown to be functionally active conglomerations of cells which may disastrously upset the physiochemical balance of the body. Through their hypersecretory effects, they lead to recognisable states the contrary of those expressions of glandular inactivity seen in myxœdema, tetany, diabetes mellitus, or Addisonism. One after another they are coming to be recognised. The relation of the thyroid adenomas to hyperthyroidism was first brought to our attention. Then came the knowledge that the adenoma of acromegaly caused its effects by an excess of a normal secretion rather than by some abnormal secretory

product as had been surmised. In its turn the association of hypertension with suprarenal tumours, particularly those composed of chromaffin cells, began to be looked upon as the symptomatic verso of Addison's disease.[1] Then the syndrome of hyperparathyroidism (osteomalacia with muscular hypotonia, multiple bone tumours, and abnormal excretion of calcium) due to a predictable adenoma of one of the parathyroid glandules was in its turn disclosed.[2] And on the heels of this discovery the conjecture that certain clinical states, which bear a symptomatic resemblance to the effects of overdosage with insulin, might be due to an adenomatous hypersecretion of the pancreatic islets has become an established fact—at the time of this writing in my own clinic an exploratory operation on a patient with recurrent attacks of hypoglycæmia has revealed a small removable pancreatic adenoma composed of islet tissue.[3] And to these known hypersecretory syndromes may now be added that caused by a basophilic pituitary adenoma, the consideration of which must, for the moment, be deferred.

How much more of this lies ahead of us may easily be imagined, and were it merely a question of recognising one after another the clinical syndromes produced by the adenomas of each particular gland, we might expect to advance with unfaltering step. But there are pitfalls in the way, and one of them is functional interdependence of these glands.[4]

THREE HYPOPHYSIAL ADENOMAS IN PARTICULAR.

That the histological structure of the anterior hypophysis is complex I need scarcely recall. There are three types of cells easily distinguishable by their differing affinity for dyes. One type, of whose function we know next to nothing, has a feebly staining non-granular protoplasm called neutrophilic or chromophobe. The other two types, of which far more is known, are characterised by a coarsely granular and chromophilic protoplasm, the granules of the one being acidophilic and of the other basophilic. These tinctorially distinguishable cells are distributed somewhat indiscriminately throughout the gland, and cytologists have been at a loss to know whether they merely represent differing stages of activity of one and the same cell, or whether they have gained morphological and functional independence. It is safe to assume that they have.

As already mentioned, there are two well-known varieties of pituitary adenoma, chromophile and chromophobe, each having its distinctive constitutional manifestations as something wholly apart from the local or pressure effects of the tumour itself—the so-called neighbourhood symptoms which chiefly call for surgical intervention. The early experimental ablations of the anterior hypophysis in adult animals (1909) taught us that a state would ensue which was wholly comparable to that accompanying the chromophobe adenomas in man, and which therefore must represent a deprivation syndrome (hypopituitarism) as opposed to the syndrome of acromegaly (hyperpituitarism). All this was in correspondence with what had been long established regarding the thyroid, and though as a working hypothesis it served a useful purpose for some years, it now proves, in one important respect, to be quite inadequate. A striking feature of the deprivation syndrome, whether observed clinically or produced experimentally, was, as we have seen, a sexual dystrophy accompanied by demonstrable regressive changes in the reproductive apparatus. That a corresponding change in the organs of sex was known to accompany the supposedly counterposed states represented by gigantism and advanced acromegaly was difficult to reconcile with the assumption that these states were a consequence of secretory over-activity pure and simple. Some unknown but predictable element governing the functions of sex was unquestionably present. This element has been disclosed.

Its discovery was primarily the outcome of Stockard's observation (1917) that in the guinea-pig ovulation could be foretold by a periodic change in the cellular character of scrapings from the vaginal mucous membrane. On testing this out in the rat, H. B. Evans discovered (1921) the existence in these animals of a clock-like four-day ovulatory mechanism; and in the effort to modify this cycle by the injection of various ductless gland preparations, he found that the emulsion of fresh anterior pituitary substance served not only promptly to interrupt œstrus but, when long continued, to cause the pathological overgrowth to which reference has already been made. When, however, the female rats in which the experimental gigantism had been produced came to be sacrificed, their ovaries were found to be greatly enlarged by an excessive and precocious luteinisation of unruptured follicles within which the ova were imprisoned, thus accounting for the interruption of œstrus. This process, as it happens, is not what leads to the amenorrhœa of acromegalic women, nor was any corresponding follicular luteinisation observed by Putnam, Benedict, and Teel (1929) in their dogs with experimental acromegaly; but the observation nevertheless gave a possible explanation for the seeming inconsistency that both hyper- and hypo-pituitary states served to inhibit the ovarian cycle.

Meanwhile, in working on the deprivation syndrome in rats, P. E. Smith showed, to make the long story short, first that the dystrophic genital apparatus could be reactivated by the repeated reimplantation of fresh anterior lobe substance, and also that these effects were more prompt and striking when that portion of the bovine gland particularly rich in basophilic elements was used for the purpose. What is more, it was learned that after castration the anterior hypophysis becomes more or less engorged with basophilic elements and that pituitary glands so modified are particularly effective in restoring experimentally produced sexual dystrophy; and soon it was discovered that precocious maturity could be induced in infant rats and mice by implantation of hypophysial tissue or by the injection of glandular extracts containing the sex principle alone.

At the time of Evans's early experiments, in which an emulsion of the fresh anterior lobe was used, the presence of two hormones was not yet suspected, but the successful separation from the gland of the two substances in active form has since been accomplished, the problem of isolating the sex substance having recently been greatly simplified by Zondek and Aschheim's happy discovery (1928) of its presence

[3] An equally clean-cut case, likewise with disappearance of symptoms after surgical removal of the adenoma, has been reported by Howland, Campbell, Maltby, and Robinson, Jour. Amer. Med. Assoc., 1929, xciii., 674.

[4] In reviewing this paper the writer is conscious of having drawn over much on the writings of his fellow countrymen. This is from no chauvinistic spirit but merely because the literature of the subject has become so vast, much of it must be taken second-hand.

in the blood and urine during pregnancy. There is much more about these later-day revelations than space can be given to recount. For my present purposes it must suffice to say that the existence of these two chemically separable principles in the anterior hypophysis obliges us to abandon, or at least to modify, the simple conception of hyper- and hypo-pituitary states as based supposedly on the effects of a growth principle alone.

Clinicians for many years have been puzzled by a peculiar syndrome (improperly called polyglandular, for all pituitary syndromes are essentially polyglandular) characterised by an exaggeration of the secondary characters of sex. That this disorder might possibly be laid at the door of the basophilic elements of the anterior pituitary was a natural assumption in view of the disclosures regarding the probable relation of these cells to the sex hormone in question. It is the prepared mind that knows what to look for, and at the autopsy on a victim of this disorder, who had died from an intercurrent infection, Dr. Teel has had the good fortune to find a small but unmistakable basophilic adenoma associated with hypertrophic changes in the ovary. It is a discovery which promises to clarify much that has heretofore been nebulous. Basophilic adenomas have been previously described, but Teel's, so far as I am aware, is the only recorded instance of a lesion of this type that has been predicted on symptomatic grounds and subsequently verified.

This independent rôle of the basophilic cells provides an explanation for the apparent symptomatic inconsistencies between the hyperpituitary syndrome of acromegaly and the opposed hypopituitary state produced by adenomas of chromophobe type in so far as both are prone to cause comparable dystrophic alterations in the organs of sex, particularly noticeable as amenorrhœa in women. The idea that the discrepancy might be ascribed to the tumour irrespective of its peculiar secretory character was the outcome of a recent study of the results of operations for suprasellar lesions that provoke what is known as a chiasmal syndrome with little or no enlargement of the pituitary fossa. Tumours of various kinds will produce this combination of symptoms, some of them being hypophysial adenomas of chromophobe type in which no secondary constitutional evidences of the lesion such as amenorrhœa were present. In other words, the normal function of the anterior hypophysis remains unaffected under these circumstances, whereas should a growing adenoma of the same type be confined within the sella, amenorrhœa will invariably appear as its first symptom.

Further to illumine this matter, the records of our entire series of verified adenomas has been reviewed by Mr. William R. Henderson, and it has been found to be generally true that whether the tumour were chromophilic in association with acromegaly or of the chromophobe variety, it was only when the pituitary fossa had become greatly expanded by intrasellar pressure that definite interruption of the functions of sex were certain to occur. Hence it may be assumed that the secretory activity of the basophilic cells, which have to do with the reproductive activities, has become inhibited purely by the effect of pressure; and, in further support of this, the fact may be mentioned that in favourable cases after partial surgical extirpation either of a chromophobe or an acidophilic adenoma in women normal menstruation may be resumed and childbearing occur.

All this, of course, applies no less to men who are afflicted with these processes than to women, and the general principle whereby an hypophysial adenoma of a given cellular type may so squeeze the cells of all other types against the relatively unyielding sellar envelopes as to render them inert, is particularly well shown by the symptomatic consequences of a chromophobe adenoma that has happened to occur in childhood. For then both acidophilic and basophilic cells are thrown out of action sufficiently early to cause cessation of growth and failure of maturation. The highly compressed residue of the gland may sometimes be histologically identified at the periphery of one of these expanding tumours.

Thus we begin to understand somewhat more clearly the nature of these anterior hypophysial tumours, whose symptomatology depends, to state the matter concisely: (1) on the elaboration of a growth inciting hormone in the absence of which dwarfism occurs; (2) on the elaboration of a gonadal stimulating hormone without which the normal maturation of the ovarian follicle cannot occur; and (3) on the presumptive elaboration of still another hormone (as yet unproved) that governs the normal function of thyroid, parathyroid, and adrenal cortex. To be sure, there is much still to learn, for the function of the cells comprising the chromophobe tumours remains unknown, but even so a distinctly forward step has recently been taken, which brings the pituitary body again to the fore after a period of doubt raised by those who were led to ascribe most if not all of its presumed functions to an independent hypothalamic source.

Tumours Affecting Neurohypophysial Mechanisms.

In the foregoing consideration of the pituitary adenomas and their symptomatology, nothing has been said, as will be observed, of that part of the dual structure in whose extracts a functionally active substance had first been detected. Indeed, by the time the sella turcica has become widely distended by a large adenoma, the posterior lobe will have disappeared without recognisable trace. Hence, from the clinical evidence furnished by the tumours of this type alone, taken in conjunction with the negligible effect of experimental ablation of the posterior lobe, it would appear that, if there is actually anything vestigial about the pituitary body as a whole, it is this very portion which first excited physiological interest.

Meanwhile, however, an hypophysial tumour of quite another type, which often begins seriously to affect the normal activity of the gland in pre-adolescence, had come to be studied with the unfolding of quite a different clinical story. Nearly a century ago (1838) Rathke had taught us how an epithelial invagination from the primitive pharynx meets the infundibular outpocketing from the base of the cerebral vesicle to form the dual gland. Naturally enough in this complicated formation with the subsequent obliteration of the craniopharyngeal duct epithelial "rests" may get sidetracked, and lead later on to anomalous tumefactions. On this basis we account for the variously named parahypophysial tumours of congenital origin which, for want of an inclusive term, may conveniently be called craniopharyngiomas.

Now these congenital tumours, which are surprisingly common, differ greatly in situation, size, and behaviour. They may be wholly intrasellar or wholly suprasellar. They may produce symptoms in pre-adolescence, or symptoms may be delayed until late in life. They vary in size from small, pea-sized cysts to huge, multilocular cystic lesions or to solid, calcareous masses as large as a tennis ball. One

thing, however, they share in common, a capacity to damage by compression one or more of the neighbouring structures, anterior hypophysis, posterior hypophysis, pituitary stalk, tuber cinereum, chiasm, and hypothalamus. Depending, therefore, upon the tumour's precise point of origin as well as upon the age at which its pressure effects begin to manifest themselves, there may be produced the greatest possible variety of local and constitutional symptoms, many of which are largely foreign to the adenomatous lesions which, up to this point, have alone been under consideration. Notable among these new symptoms are polyuria and adiposity in varied combinations with impaired growth and sexual dystrophy.

HYPOTHALAMUS V. HYPOPHYSIS.

It has been said that if some unusual clinical condition turns up concerning which one seeks information, an account of it is likely to be found in Jonathan Hutchinson's Archives. To this I would like to add, particularly for the benefit of neurologists, that if Hutchinson fails them, try Byrom Bramwell. In his much neglected book on intracranial tumours published in May of 1888, only two years after Marie's description of acromegaly, it is stated:

> "Tumours of the pituitary body are in many instances attended with an excessive development of the subcutaneous fat, and in some cases with the presence of sugar in the urine, or with simple polyuria (diabetes insipidus). Whether these symptoms are due to the fact that the pituitary body itself is diseased, or whether, as seems more likely, to the secondary results which tumours in this situation produce in the surrounding cerebral tissue, has not yet been decided. Possibly, as Rosenthal has suggested, the diabetes, which is sometimes present, may be the result of secondary changes produced in the grey matter of the floor of the fourth ventricle. He supposes that the pressure of the tumour first produces irritation of the grey matter lining the third ventricle, and that this irritation travels along the grey matter which connects the third and fourth ventricles and produces secondary changes in the latter."

Medicine was not yet prepared to grasp the significance of this truly prophetic statement; indeed, at the time it was written it was not as yet known with certainty that the malady of Marie had any relation to the pituitary body and, clinically speaking, the "grey matter lining the third ventricle" was undiscovered country. Thirteen years elapsed before Alfred Fröhlich's description of one of these cases was published as an example of "hypophysial tumour without acromegaly," which shows how confused were the ideas of pituitary function in those days of the widely discussed syndrome of adiposo-genital dystrophy. Much still remains obscure, but one can at least now clearly see that the skeletal and sexual infantilism which accompanies such of these tumours as begin to cause symptoms in childhood is due to compression of the anterior hypophysis with consequent inactivation of the acidophilic and basophilic elements that provide, as we have seen, the hormones of growth and sex. The dwarfism and sexual dystrophy which often accompany these tumours thus become easily explained, and the same is true of the visual disturbances common to all tumours of this region that press against the chiasm; but when we come to the other manifestations of these hypophysial-duct tumours, we find ourselves on less secure ground.

The detailed post-mortem study of one of these lesions found in the body of an adult adipose dwarf led Erdheim (1916) to express the view that adiposo-genital dystrophy is nothing more than pituitary dwarfism *plus* adiposity, the latter feature of the syndrome being ascribable to an involvement of the base of the brain—*adipositas cerebralis*. Thus nearly 30 years after Bramwell's statement, attention was again drawn to the possible participation of the hypothalamus in the symptomatology of pituitary lesions. And when this revived conjecture came to be followed a few years later by the disclosure at the hands of Camus and Roussy (1920) and of Bailey and Bremer (1921) not only that an experimental polyuria can be produced by injuries restricted to the tuber cinereum but that adiposity, sexual dystrophy, and as Roussy believed even dwarfism as well, might sometimes ensue, our accepted views of the relation of these symptoms to the pituitary body itself were badly shaken. One or another of these authors, independently, have gone so far as to express doubts as to whether loss of the hypophysis played any part whatsoever in the hypopituitary effects previously ascribed to it—a challenge which produced a veritable bouleversement of our cherished preconceptions.

Because of these disclosures, most of the earlier experimental hypophysectomies on dogs now unquestionably lie open to the just criticism first raised by Aschner (1912) that a coincidental damage of the adjacent tuberal nerve centres probably accounted for the post-operative polyurias, glycosurias, as well as the more tardy adiposity and genital atrophy that not infrequently supervened. Whether the canine gland was approached from below through the pharynx or from the side by elevating the temporal lobe, these secondary symptoms were apt to ensue. In the rat, however, as in man, the gland is overlain by a dural diaphragm merely perforated for the passage of the stalk, so that either the nervous tissues and pars tuberalis above or the body of the gland below can be separately subjected to experimental lesions. Taking advantage of this fact, P. E. Smith, after devising a parapharyngeal method of exposing the gland in these animals, has shown [5] that a sub-diaphragmatic hypophysectomy only leads to those inhibitions of growth and of sexual activity with which we are now familiar; when, on the other hand, the tuber is injured by a supradiaphragmatic injury, an adiposity, which at times is truly astounding, may be produced with little if any secondary effect on the functions of growth and sex. Though Smith has made no mention as yet of polyuria in his highly important series of papers, this want has just been supplied by Richter,[6] who, by an accurately placed stab-wound through the base of the rat's skull just anterior to the hypophysis, has produced a persistent polyuria in a series of animals (a ten-fold increase in one instance) in the absence of any ensuing adiposity. By these experiments a strictly hypothalamic syndrome as opposed to a strictly pituitary one has seemingly therefore been produced, there being no apparent overlap in the symptoms.

In consequence of all this, the attention of neuro-anatomists, pathologists, physiologists, and psychiatrists who share an interest in the nervous system has come of late years to be riveted on that much neglected portion of the palæo-cerebrum which lies, roughly speaking, within the bounds of the Willisian circle. In the walls of the third ventricle, with its dependent infundibulum and tuber, various clusters of nerve-cells have been described with complicated tracts running between them. It has come to be appreciated, meanwhile, that these centres are particularly vulnerable to the effects of encephalitis after which diabetes insipidus, obesity, somnolence, and so on are frequently observed. What is more, experimental hypothalamic injuries, other than those confined to the

[6] Richter, C.: Experimental Diabetes Insipidus, Brain, 1930, liii., 76.

tuber, which so markedly disturb the water balance and fat deposition, have disclosed in the anatomically insignificant 'tween-brain hitherto unsuspected activities, vegetative and emotional, of utmost functional consequence, the separate consideration of which must for the moment be postponed.

The Posterior Hypophysis.

It will be seen from what has gone before that, during the past decade, attention on the one hand, with great profit, has come to be focused on the anterior hypophysis which proves to be the "moderator" of the endocrine series, and that, no less profitably, attention has been drawn in the other direction to the fundamentally significant area at the base of the brain known as the diencephalon. The posterior lobe, meanwhile, has lain unattended in the shadow between these two fires, though there are abundant reasons, other than the known activity of its extracts, for lifting it from its obscurity. Certain of these reasons, both developmental and histological, may be mentioned.

That portion of Rathke's pouch which comes in contact with and ultimately envelopes the down-growth of nervous tissue comprising tuber and pars nervosa acquires epithelial characteristics quite different from those of the highly vascularised pars anterior. Indeed, this contact is essential for the normal development of the gland, as has been shown by the non-appearance of the infundibular protrusion in the tadpole when the epithelial component of the future gland has been cleanly removed, and by its normal development if a mere epithelial fragment is left behind; and what is more, as recently shown by Blount,[7] the epithelial rudiment of the gland when transplanted in amphibian embryos fails to develop unless some of the nervous tissue is taken with it.

Histological evidences of activity are based on the presence of a demonstrable secretory product and on the presence of non-myelinated nerve-fibres. In the fully formed adult gland under certain experimental or pathological conditions, one may see viable pars intermedia cells streaming into the posterior lobe in great numbers. Even under normal circumstances, as first described by Herring (1908), the epithelial cells of the pars intermedia appear to invade the pars nervosa becoming transformed into hyaline bodies which stream upward toward the ventricle between what appear to be loosely textured, long-drawn-out tails of ependymal glia. It has been shown, moreover, that if the hypophysial stalk is mechanically obstructed, the secretory product becomes dammed back in the lobe which becomes turgid with hyaline. There is strong evidence, therefore, to indicate that these Herring bodies represent the secretory principle which acts either directly on the nervous centres of the tuber, as some assume, or actually passes between the ependymal cells into the infundibular cavity as others have believed. As a matter of fact, under either assumption it might well enough affect the nerve centres, one of the more important of which lies directly under the ependyma, and evidence will be presented to show that posterior lobe extracts are far more potent when injected into the cerebral ventricles than by any other method of administration.

When studied by ordinary methods of fixation and staining, the posterior lobe has a nondescript appearance. The hyaline is usually dissolved out of its channels, and some chemical property in the lobe apparently counteracts the usual effect of the special stains for which glia and nerve-fibres elsewhere show marked affinity. When successfully stained, however, non-myelinated nerve-fibres [8] in abundance, as first clearly demonstrated by Greving [9] and by Pines,[10] can be traced from both the supraoptic and paraventricular nuclei (though more particularly from the former) to converge at the infundibulum, whence in a compact bundle they pass down the pituitary stalk to enter the posterior lobe. Arrived there, they not only ramify widely throughout the pars nervosa weaving themselves, as Greving states, in "basket-like" fashion around what appear to be secretory islands, but they also, according to Pines, can be traced in among the epithelial cells of the pars intermedia. With this the recent observations by Croll [11] and unpublished studies from my own laboratory are in full agreement. Nor, in my opinion, has due consideration in interpreting the effects of these tuberal injuries been laid on the fact that they are likely to interfere with the blood-supply to the gland, a certain amount of cerebral necrosis in the pars anterior being the usual consequence of stalk separation.[13] What is more, experimental evidence is accumulating which speaks in favour of the view that the epithelial investment of the infundibular lobe, whether as pars intermedia or pars tuberalis, has essentially the same function. In one or all of these three factors—nerve-supply, blood-supply and epithelial cuff of tuber—lies the probable explanation of much that has been contradictory in regard to the effects of experimental hypophysectomy as opposed to injuries of the tuber, more particularly in the dog, but probably in the rat as well.

This intermediary neuro-epithelial structure, therefore, cannot be lightly pushed aside in our temporary excitement over the diencephalon and its newly disclosed functional importance. Whether the several known responses to the injection of its extract are due to a single chemical substance or to more than one, is less important than the knowledge that striking physiological effects ensue—*hæmodynamic, antidiuretic, and oxytocic*—to which *pigmentary, galactagogue, antipyretic*, and *sudorific* effects may possibly be added. Let us, in the order of their discovery, take up these known responses and see what can be learned in behalf of this symptomatically neglected portion of the gland.

THE BLOOD-PRESSURE-RAISING EFFECTS.

Whereas in all studies of adrenal function the hæmodynamic properties of its extracts overtop all else, the comparable effects produced by an extract of the posterior hypophysis have been entirely lost sight of. Had not physiologists so conclusively shown that the rise in blood pressure which accompanies emotional states was associated with an increase

[7] Proc. Nat. Acad. Sci. (Washington), 1930, xvi., 222.

[8] In our experience they are best shown by De Castro's method, but the tissue must be removed and fixed at the earliest possible moment after death.

[9] Greving, R.: Klin. Woch., 1925, iv., 2181; also Deut. Zeit. f. Nervenheilk., 1926, lxxxix., 179.

[10] Pines, I. L.: Zeit. f. d. ges. Neurol. u. Psychiat., 1925, c., 123.

[11] Croll, M. M.[12]: Jour. Physiol., 1928, lxvi., 316.

[13] This abundant nerve-supply from interbrain to gland was unknown to the "hypothalamists" whose revolutionary papers appeared chiefly from 1920 to 1922, but there nevertheless lay before them the inescapable fact that extracts of the posterior lobe could check the more immediate and striking of the symptoms their tuberal injuries provoked.

[13] Dandy and Geotsch, at the writer's suggestion some years ago (Amer. Jour. Anat., 1911, ii., 137), described merely the chief source of the arterial supply to the canine gland. There has been great need of further and more detailed studies of the entire circulatory apparatus; and this want, I am permitted to state, has been filled by Pota and Flemming whose paper entitled A Portal Circulation from the Pituitary to the Hypothalamic Region will shortly appear in the Journal of Anatomy.

of adrenalin in the blood, one might have expected that between the two, posterior hypophysis and adrenal, the pressor response would more likely be due to a discharge of its active principle from the former which is near at hand, while the pathway to the adrenal is devious and long. In favour of this would be the recent knowledge that among other uncontrolled reactions, emotional explosions with an accompanying rise in blood pressure occur in an animal whose cortical inhibitions have been removed by severing the nervous pathways that pass from the frontal cortex to hypothalamus. The matter, indeed, might well be worth looking into as a possible cause of emotional hypertension, most other likely sources of information to explain these states having been exhausted. A surgical clinic, however, has less to do with irritative or emotional processes than with destructive ones produced by tumours and these, apart from the functionally active adenomas I have mentioned, can only be expected to evoke symptoms due to loss of activity.

Most patients with craniopharyngiomas which have served to compress the pituitary stalk, as these tumours usually do, have an unaccountably low blood pressure. Even in adults, a systolic pressure in the 90's is common, and registrations of 85/60 in a patient of 21, of 60/50 in a patient of 23, and of 80/60 in a patient 30 years of age occur in the hospital series. Still more to the point is the fact that patients with large chromophobe adenomas, which remain confined within the sella and compress the posterior lobe but leave the hypothalamus unaffected, usually have a relatively low systolic blood pressure (below 100 in 11 per cent. and below 110 in 46 per cent. of the cases). Beyond this we have nothing much to go on. What is more, confession must be made that two out of our series of 243 patients with verified chromophobe adenomas had coincidental vascular hypertension.[14] In want of a satisfactory explanation of these exceptions to the general rule, it must be admitted that from a clinical point of view the posterior lobe has no such definite influence on blood pressure as the laboratory experiences with its extract would have led us to expect. It may be that the clinic had been misled, as it was in regard to the presumed diuretic effects of the extract, and the fact that when injected into the ventricle in man it may cause marked peripheral vaso-dilatation with a fall in pressure rather than a rise possibly points in this direction.

THE ANTIDIURETIC EFFECTS.

How it is that the polyurias produced by various tuberal lesions can be counteracted by the injection of posterior lobe extract remains unexplained by those who ascribe to the hypothalamus an independent rôle in the production of the phenomenon. Doubtless in all the experiments of years past, too much attention had been paid to the symptoms of thirst and polyuria and too little to symptoms the opposite of these, oliguria having been observed not infrequently as a sequel of our early (1908–10) canine hypophysectomies. It may be stated, however, that the large intrasellar adenomas which are almost certain to obliterate the posterior lobe are not accompanied by polyuria, unless in the process of removing one of them the ventricular wall adjacent to the chiasm should happen to be injured. This would speak strongly in favour of the independent hypothalamic origin of diabetes insipidus were it not for the abundant nerve-fibres that sweep around both sides of the chiasm and descend in the walls of the infundibulum to their destination in the posterior lobe.

Owing to a continued interest in the problem of how the active principle of this part of the gland gets into operation, some further experiments have been made by Dr. Maddock in the surgical laboratory at Harvard by the application of silver "clips" at various levels on the hypophysial stalk. That such an occlusion of the stalk leads to a damming back of the hyalinoid substance elaborated in the posterior lobe, first reported with Emil Goetsch (1910), was again alluded to in my Cameron Lectures (1925); but what is more pertinent to our present theme is that polyuria may be produced in this way without extravasation of blood or such widespread damage as the experimental punctures are likely to occasion. In one of Dr. Maddock's animals, an enduring polyuria, which at times averaged above five litres per diem, ensued and, in the absence of any tendency to adiposity or other recognisable symptoms, persisted until the animal was sacrificed nearly two years later.

Thus, in contrast to the temporary polyurias usually produced by canine hypothalamic punctures, this clip experiment led to a more permanent disorder fully comparable to clinical diabetes insipidus. In seeking an explanation for this, I incline to the view that in the puncture experiments some of the conducting paths rather than the actual nerve centres have been damaged,[15] whereas the clip not only served to interrupt the nerve impulses to the posterior lobe but at the same time mechanically obstructed its secretion, a combination of circumstances that obtain in those tumours of the region with which diabetes insipidus is so often associated.

All this admittedly leaves unexplained why a more marked temporary polyuria does not follow the simple removal of the canine posterior lobe unless we accept Trendelenburg's recently expressed views regarding the vicarious action of the residual pars tuberalis. Indeed, it is yet a matter of uncertainty as to whether polyuria after all is a paralytic or an irritative phenomenon, for though it is commonly assumed to be the former, the familiar emotional polyurias would suggest the latter. But the experimental evidence so far contains much that is contradictory, and not until it will be possible to evolve some method of first stimulating and then of destroying the definite cluster of nerve-cells (presumably the nucleus supraopticus) which govern the response can we begin to feel that we have touched bottom in this watery topic.

THE OXYTOCIC RESPONSE.

The discovery by Dale (1906) of the specific action of posterior lobe extracts on smooth muscle, more particularly noticeable on the musculature of the pregnant uterus, has led, as is well known, to their employment in cases of delayed parturition. It was the experience of all, in the earlier experimental hypophysectomies, that when they were undertaken on a pregnant animal, abortion was inevitable, presumably from the setting free of secretion, though it is not impossible, as Ashner believes, that the effect was due to a coincidental damage of the tuber. This could be easily determined by observing the effect of an isolated tuberal injury in the pregnant rat, but so far as I know such a test has not been made. It

[14] It should be pointed out that these hypopituitary states are usually accompanied by a greatly lowered basal metabolic rate to which the vascular hypotension might well enough be ascribed. Opposed to this assumption is the fact that the two patients with definite hypertension also had a low basal metabolic rate.

[15] In Richter's prolonged puncture-polyurias in the rat (loc. cit.), it may be assumed that the supraoptic nucleus was the site of the lesion.

has been shown, however, by P. E. Smith that after total hypophysectomy in the rat, which leaves the tuber untouched, the muscle-fibres of the uterus atrophy and lose their wave-like contractility, and the fact that the fibres can be restored to their normal state by hypophysial implantations serves to exclude the hypothalamus from any possible participation in this effect at least.

The peculiarity will not escape attention that the reproductive cycle, after the act of mating, is inaugurated by discharge of the pars anterior sex hormone which initiates the sequence of events that lead to ovulation, whereas, on the other hand, the posterior lobe secretion facilitates the termination of the cycle by expelling the fœtus, both processes in all probability being related to some primary neuro-glandular impulses.[16]

The extract also acts, though less strikingly, on the smooth muscle of other organs than the uterus—on that of the intestine, for example. It increases intestinal peristalsis and particularly when injected intravenously may have a prompt cathartic effect. On the other hand, patients with tumours which have destroyed the pars nervosa or thrown it out of function by compression are, in many instances, notably victimised by troublesome chronic constipation.

PIGMENTARY EFFECTS.

Although the standardised rat threatens to usurp the place once occupied by the frog as the principal contributor to physiological knowledge, the frog and its larvæ still have ample contributions to make. Not only has embryology taught us that the rudimentary hypophysis is the first of the future endocrine organs to be differentiated, but in the tadpole its exposed position lays it open to surgical removal. When so removed, as first shown (1916) independently and brilliantly both by Allen and by Smith, the growth of the tadpole is checked, metamorphosis does not occur, and the pigmentary system is so affected that the embryo acquires a silvery or albinous appearance owing to the contraction of the cutaneous melanophores. Reimplantation of the hypophysis or the parental injection of fresh pituitary emulsion serve to counteract all these effects; but of especial interest is the fact, of late strongly re-emphasised by Allen,[17] that transplants of the pars intermedia from adult frogs into these albinoid tadpoles, while without effect on growth or metamorphosis, serve within a few hours permanently to expand the melanophores with darkening of the skin. Here, then, is evidence of still another peculiar property of posterior lobe extracts which must be taken into consideration—their influence on the metabolism of dermal pigments.

It is curious that the principal pigmentary disorder which is clinically recognised is that associated with Addison's disease, the adrenal glands, as may again be recalled, being in a certain sense (the analogy cannot be pushed too far) a fused neural and epithelial structure somewhat akin to the pituitary body. Pituitary disorders, though less conspicuously so, are likewise accompanied by appreciable pigmentary disturbances, and, in passing, attention may be drawn to the reputed exemption of the negro to endocrine disorder of any kind. The complexion of an acromegalic, as is well known, noticeably darkens in colour, whereas the reverse is true of hypopituitary states in which the skin shows in addition to its other distinctive peculiarities a characteristic pallor. Presumably, from the inability of the body to elaborate melanin, the skin of these patients no longer pigments readily on exposure to the sun, and when it does so, the exposed parts are apt to be freckled rather than uniformly darkened. Whether this peculiarity of hypopituitary states would be overcome by the administration of posterior lobe extracts has, so far as I know, never been tested.

GALACTAGOGUE ACTION.

Posterior-lobe extracts were claimed by Ott and Scott (1910) to have the property of augmenting the quantity of milk in the lactating goat, and they have since gained repute as a means of increasing the diurnal yield of cows. Whether this property has any bearing on the extraordinary prolongation of the period of lactation which sometimes afflicts acromegalic women after childbearing seems most unlikely. Examples of continued lactation for as much as seven years has been recorded, and in one of my patients it has persisted for over five. It is reasonably certain that a hormone from some source incites the mammary changes that accompany lactation, but it is more probable that it is liberated from some pelvic organ modified by the chain of events accompanying pregnancy than that it should hark back to the pituitary body (far less its posterior lobe) which set these events going.

The possibility that posterior-lobe extract may exercise an hitherto unobserved *antipyretic effect* and also a *sudorific effect* has been suggested by the lowering of body temperature and by the profuse sweating that follows the injection of pituitrin directly into the ventricle. There will be occasion to return to this possibility later on.

(To be concluded.)

[16] Fontes (Compt. rend. Soc. de Biol., 1929, cii., 227) claims to have shown the presence of oxytocic properties in the blood at the time of labour.

ON THE VALUE OF RAMISECTION IN CASES OF SPASTIC WEAKNESS.

BY

C. P. SYMONDS, H. A. T. FAIRBANK,
A. S. BLUNDELL BANKART, G. PERKINS,
W. R. BRISTOW, W. GORDON PUGH,
R. C. ELMSLIE, W. H. TRETHOWAN,
E. LAMING EVANS, P. J. VERRALL.

THE operation of ramisection, or division of the sympathetic rami to the limbs, was devised by J. I. Hunter and N. D. Royle in the course of some experimental observations upon muscle tone in animals. It was subsequently employed by Royle in the treatment of spastic weakness in human beings, on the assumption that the nervous impulses responsible for the hypertonus in such conditions are conveyed by the sympathetic efferents. Royal and others have reported a considerable number of successful results from the operation. On the other hand there have been adverse reports. The purpose of this communication is to record the observations made by several independent witnesses upon six cases in which the operation was performed by Royle himself while on a visit to this country in 1927.

The patients were selected by Royle from a number of children afflicted with spastic weakness of various kinds as being marked cases of spasticity likely to benefit from ramisection. The operations were performed by him during the months of May and June, 1927, at Queen Mary's Hospital, Carshalton. The

patients were throughout under the care of Mr. Gordon Pugh, who was responsible for the supervision of post-operative care, massage, and re-educative exercises, this being planned upon the lines advised by Mr. Royle. Both before and after operation these patients were seen by a number of orthopædic surgeons and one or two neurologists. Their post-operative condition was reviewed in June, 1928, by a group comprising Messrs. Bankart, Bristow, Elmslie, Fairbank, Verrall, Perkins, and Pugh; on this occasion all six patients were examined and their state compared with that recorded in the preoperative notes. In March, 1929, their history was again reviewed by Messrs. Bankart, Bristow, Fairbank, Laming Evans, Pugh, Trethowan, and Dr. Symonds. At this meeting three of the patients were examined; notes were made of their condition and compared with those made by Mr. Gordon Pugh and by others before operation. One had been unanimously considered unimproved at the meeting of June, 1928. Dr. Symonds was deputed to visit, examine, and report upon the two remaining patients.

Results in Six Cases.

The notes of these cases provide too large a mass of material for publication in extenso. They have been compiled in full, reviewed, and summarised as follows:

In *Case 1*, presenting a combined extra-pyramidal and pyramidal rigidity and weakness of left upper and lower limbs following encephalitis lethargica, cervical and lumbar ramisectomy resulted in an immediate post-operative reduction of rigidity with increased freedom of voluntary movement. Within a week of the operation the spasm of the arm was returning, though the leg was still improved. Thirteen months later the patient's condition was as before the operation and remains so at the present time.

In *Case 2*, presenting a bilateral rigidity and weakness of a purely extra-pyramidal type after encephalitis lethargica, double lumbar ramisectomy produced no improvement.

Case 3 was that of a boy presenting at the time of operation a left hemiplegia which had come on acutely six and a half months previously either as a result of a polio-encephalitis or as a manifestation of congenital syphilis. In this case left cervical and lumbar ramisection were followed by a slight, but definite, diminution of rigidity and increase of voluntary power. In the opinion of Dr. Symonds, however, the amount of improvement shown was such as might reasonably have been expected with re-educative treatment alone in a case of hemiplegia from vascular or inflammatory cause with a history of acute onset only six and a half months before. He considered, therefore, that the improvement which undoubtedly followed operation could *not* fairly be attributed to it.

In *Case 4*, a severe spastic quadriplegia, bilateral lumbar ramisectomy resulted in some quite temporary improvement.

Case 5 had been noted by Mr. Trethowan several months before ramisectomy was entertained as "not a very bad case" of spastic quadriplegia, able to walk with a little help. There is no evidence to show that bilateral lumbar ramisection in this case produced any result, such improvement as was ultimately seen being accounted for by the lengthening of the tendo Achillis on both sides which was subsequently performed.

In *Case 6* a right hemiplegia of old standing, cervical and lumbar ramisectomy were followed by temporary improvement, with subsequent return in the course of a few months to the preoperative state. A chance observation upon this patient illustrates the importance of continuous educative exercises, for during a period of six weeks, while these had to be discontinued, she relapsed into a condition worse than that noted since her admission.

Conclusions.

1. The operation of cervical or lumbar ramisection as performed by Mr Royle is without effect upon the rigidity from extra-pyramidal disease.

2. The rigidity of pyramidal disease as seen in conditions of hemiplegia or quadriplegia in children may be temporarily diminished after the operation. This temporary diminution of tone has been observed in both upper and lower limbs with some improvement of voluntary power. The diminution of tone and improvement of function are, however, short lived, and within a few weeks or months, notwithstanding continuous measures of re-eduction under experienced medical supervision, the condition of the patient remains as before the operation. In the opinion of several of the surgeons who examined these cases both before and shortly after operation, the diminution of tone was no more than may be seen after *any* major surgical procedure with post-operative shock.

3. The operation therefore appears to have no place of value in the treatment of spastic weakness.

4. The observations recorded show that in young human beings the sympathetic fibres play no rôle of any importance in the maintenance of muscular rigidity, whether this is of the so-called parkinsonian variety or of the type seen in lesions of the pyramidal tracts.

INTRAVENOUS PYELOGRAPHY.*

BY FRANK KIDD, M.CHIR. CAMB.,
CONSULTING SURGEON TO ST. PAUL'S HOSPITAL, LONDON.

THE discovery of cholecystography by Graham stimulated the search for an iodine-containing substance capable of being picked up out of the blood stream by the kidneys in a concentration of such intensity as to enable pyelograms, ureterograms, and cystograms to be taken. Roseno devised such a substance, consisting of sodium iodide joined to a urea molecule, named pyelognost. It has to be given in large doses and appears to be somewhat toxic, so that it has not been widely adopted for clinical application. It enabled Roseno to report some observations of considerable interest on the physiology of the ureter.

Prof. Arthur Binz, a pupil of Ehrlich, was working in Berlin on organic compounds of iodine, particularly selectan neutral. Prof. von Lichtenberg and one of his assistants, Dr. Swick, of New York, enlisted his help to try out on animals and later on human subjects a series of substances related to selectan-neutral. Prof. Binz provided them with a substance derived from selectan neutral belonging to the pyridine group which appeared to possess the properties for which they were seeking. To this substance they have given the name of uroselectan. It has an iodine-content of 42 per cent., and is readily dissolved in water, the solution being neutral. Swick found that 180 g. of the substance dissolved in water could be injected intravenously into a man weighing 60 kg. without danger of poisoning. He found that in persons with normal kidneys 15 minutes after the injection no more iodine could be recovered

* Being the substance of a lecture delivered before the Windsor and District Medical Society on May 29th.

from the blood stream, and that 90 per cent. to 95 per cent. of the substance could be recovered *unchanged* from the urine within eight hours. The iodine exists in the molecule in a very stable organically bound state. Iodine in large doses appears to be toxic only if injected in an inorganic ionised state. The substance seems to possess the peculiar property of passing through the renal tubules and out of the body in the urine without being changed in any way and without giving off any ionised iodine. This appears to be the explanation of why it does not give rise to iodism.

Use of Uroselectan.

For clinical purposes Swick and von Lichtenberg have been using 40 g. uroselectan dissolved in 100 c.cm. of distilled water. They used it in 119 cases with one death, a case of nephrosis that died of uræmia 19 hours after the injection. The injection is given *slowly* into a vein and radiograms are taken a quarter of an hour, three-quarters of an hour, and one and a quarter hours after the injection, and for even longer if necessary. If both kidneys are normal in function, within a few minutes the bladder is full of the substance and a clear picture of its outline is thrown on the X ray plate. At the same time the substance of the kidneys being full of the drug are rather densely outlined and dim shadows begin to appear of the pelvis and parts of the ureter. After half an hour to an hour the shadows of each pelvis and of the ureters may show up reasonably well, though usually not so distinctly as when filled from below by means of sodium iodide. In a little more than half of the cases the pictures are dense enough to enable a trained urologist to form an opinion as to the anatomical condition of one or both kidneys. If, on the other hand, one or both kidneys are deficient in function it may take many hours before the pelvis of the kidney fills up at all, particularly in cases of inflammation or tumour. Where, however, there is a one-sided obstruction to the ureter or an obstruction in the urethra more satisfactory pictures are obtained as the substance accumulates above the obstruction in a high concentration. The patient must micturate between each exposure as the bladder becomes opaque and obscures the lower ends of the ureters.

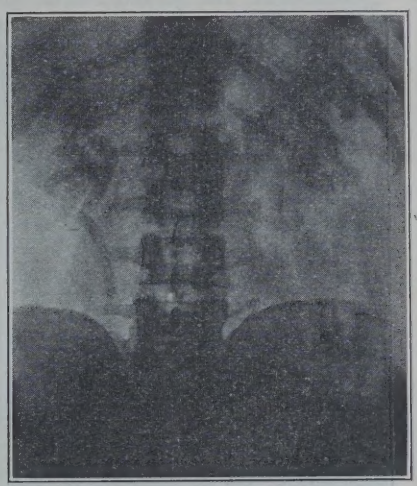
FIG. 1.

(Case 1.) Tuberculous left kidney; calcified obliterated left ureter.

By the courtesy of Prof. von Lichtenberg, to whom I extend my warmest thanks, I was presented with advance samples of uroselectan, and this enabled me to publish in the *British Journal of Urology* the first account in this country of the method, with a description of my first case which was injected on Dec. 18th, 1929.

The exact technique for preparing the substance for injection is furnished with each sample of the drug. Suffice it to say that the preparation has to be exact and should be carried out by chemists accustomed to the preparation of intravenous solutions. Each injection must be freshly prepared. The solution appears of a brown colour. This is not due to the presence of free or dissociated iodine, but is purely an optical effect due to the great weight of the molecule and is said to be typical of all pyridine compounds. The solution has been boiled continuously for three hours without the production of any free iodine. Mr. Ward, of the Crookes Laboratories, has examined a specimen for me. He states that its solution contains no free iodine even when boiled and kept at a temperature of 100° C. for one week, or when autoclaved at 120° C.

FIG. 2.



(Case 2.) Stone blocking the right lumbar ureter.

The drug cannot be given by the mouth as it is said to cause vomiting. As the injection is being given the patient may complain of a buzzing in the head, of a general feeling of warmth, and sometimes of thirst and slight giddiness. Some of the patients also complain of cramp in the arm which is being injected. Apart from these symptoms the injections in my hands have been free from unpleasant effects.

TOXICITY.

As yet, though the drug has been given in a considerable number of cases, no clinical evidence has appeared to suggest that the drug causes any damage to the tissues in general or to the kidneys in particular. It is true that death occurred within 24 hours after an injection in one of Swick's cases, but this happened when the drug was given to a patient already suffering from uræmia as a result of nephrosis. Experience suggests that the drug should not be used when both kidneys are known to be severely damaged. A careful clinical examination should usually suffice to exclude such cases, and probably it is a wise precaution to estimate the blood-urea in all doubtful cases before giving an injection. Heritage and Ogier Ward obtained a kidney at autopsy some little time after an injection, and the pathologist, Dr. Brewer, stated as a result of his examination that it indicated that the renal tissue had suffered no acute damage from the use of uroselectan. Prima facie it is difficult to believe that the delicate secreting cells of the kidneys are not physically damaged when they are asked to thrust such heavy molecules out of the blood stream into the urine in so short a space of time. Experiments on animals are being carried out to throw further light on this question. The evidence at present available with regard to toxicity justifies the use of uroselectan in chosen cases, but a further period must elapse before it is safe to say that it should be used freely for routine examinations.

Results.

I have used uroselectan in 17 carefully selected cases, that is to say, in cases where I thought it was likely to yield additional information of value, or in cases that had been cystoscoped by others previously and whose experiences led them to prefer a method which might enable them to avoid another cystoscopy. There were four cases of stone, four of hydronephrosis, one of renal tumour, three of tuberculosis, two of doubtful renal pain, and three of pyelitis. The answer given was satisfactory in 11 cases, doubtful in three cases, and of no value at all in the remaining three cases. In one case the answer was wrong. It was thought that a renal tumour was present; the kidney proved on removal to be full of multiple abscesses.

FIG. 3.

(Case 3.) Hydronephrosis right kidney; healthy left kidney.

Cases of stone and hydronephrosis yielded the best pictures, cases of tumour and pyelitis yielded poor pictures. One patient vomited while the drug was being given, but the condition of the others gave no cause for anxiety, and there were no unpleasant after-effects.

I have selected four of the best cases for illustration. One cannot expect to get such definite pictures in every case, and unless this is borne in mind an unduly favourable idea of the method will be gained.

CASE 1.—Female, aged 58 years. Many years intermittent pain in left loin. Tender swelling in left loin without bladder symptoms. The urine was clear, the left ureter was completely blocked, the bladder was healthy. Uroselectan revealed a large tuberculous sacculated kidney completely destroyed, with calcification of the left ureter.

CASE 2.—Male, aged 28 years. For a long time repeated attacks of violent right-sided colic. Doubtful shadow in region of right lumbar ureter. Cystoscoped elsewhere without diagnostic result. Unwilling to undergo further cystoscopy. Uroselectan showed that the shadow was a stone blocking the right ureter. The left kidney came out very poorly in this case. The stone had to be removed by operation as the patient refused to try cystoscopic removal.

CASE 3.—Male, aged 45 years. Four years right renal colic, hæmaturia, wasting. Refused cystoscopy. Uroselectan showed a healthy left kidney, a large hydronephrosis on the right side. Confirmed at operation.

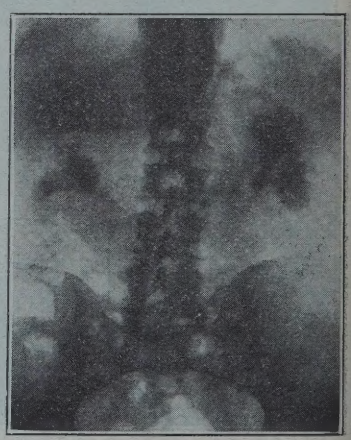
CASE 4.—Male, aged 60. Three years pain in left loin and hæmaturia. Large shadow in region of left kidney. Uroselectan showed a healthy right kidney, the left kidney pelvis blocked by a stone with more than half the kidney substance destroyed.

Kidneys the subject of severe infection, pyonephrosis, or advanced tumour appear to excrete uroselectan poorly and so may fail to yield a picture; whereas kidneys with back pressure, even if considerably destroyed, appear to show up better as the drug accumulates above the obstruction. Where both kidneys are subjected to back pressure we do not yet know if the drug is likely to prove toxic. The method should not therefore yet be employed as a routine method before cystoscopy, and will be needed less often in the case of women than of men. Suitable cases ought to be picked by men skilled in urology, otherwise mistakes are likely to arise and accidents to happen. Clinical signs of mild or threatening renal failure should be searched for, and in cases of doubt the blood-urea should be estimated. The urologist is in the best position to say in any given case as to whether cystoscopy is necessary or desirable before or after the use of uroselectan. There are many things that can be learnt by cystoscopy that cannot be revealed by intravenous pyelography, and that are essential for a complete diagnosis—for instance, the nature of a chronic cystitis or a tumour of the bladder.

When should the Method be Used?

Intravenous pyelography would have obvious advantages if it were proved to be entirely non-toxic, and if it gave satisfactory pictures in a fair proportion of cases. The discomfort associated with cystoscopy could sometimes be avoided, and the method seems to give indications of the functional power of each kidney, in addition to anatomical pictures of the urinary tract. At present, however, it should be reserved for use in difficult cases where cystoscopy and catheterisation of the ureter are difficult, dangerous, or impossible—e.g., where one ureter is so blocked by stone or stricture as to prevent the passage of opaque medium upwards into the kidney; in cases of very profuse hæmaturia; in severe cystitis; in certain cases of stricture of the urethra and enlarged prostate unassociated with chronic uræmia; in cases where one or both ureters open in abnormal positions after resection of the bladder, after implantation of the ureter into the bowel, in cases of ectopic ureter; in cases of vesical pouch to show the relation of the ureter to the pouch; in cases of ureters damaged at operation and the subject of fistulæ.

FIG. 4.



(Case 4.) Stone blocking the pelvis of the left kidney.

In most cases of hæmaturia the urologist would hesitate at the present moment not to employ cystoscopy. By this means he may at once detect a papilloma of the bladder, or he may be able to determine that the blood is coming from one ureter only. In such a case he would at once take an ordinary pyelogram of the bleeding kidney. To defer cystoscopy in such a case in the hope of obtaining complete information by intravenous pyelography would be unwise and hardly fair to the patient, especially when it is realised that renal tumours secrete the drug poorly if at all, give poor pictures, and are liable to be mistaken for inflamed kidneys.

Again, in the average case of tuberculous cystitis far more definite indications for operative interference

can be obtained by cystoscopy, and the intravenous method would only be used subsequently to confirm its results and possibly to throw some further light on the case. The results in tuberculosis were not decisive in two out of three cases.

In case of *Bacillus coli* cystitis in men, if the prostate has recently been acutely inflamed it is wise to defer cystoscopy. Intravenous pyelography may in such cases throw light on the state of the kidneys. But if one of the kidneys fails to excrete enough uroselectan to throw a shadow the only permissible conclusion is that that kidney is infected and only temporarily out of action. The finding does not necessarily mean that the kidney has been permanently damaged.

As a routine in cases of enlarged prostate and stricture of the urethra it is doubtful whether the method can be relied upon to give evidence valuable enough to justify the increased risk that its use entails in those particular cases. Where, however, one ureter is partially blocked by stone or other form of obstruction the conditions are ideal for getting the most out of the method with the least risk. It will undoubtedly prove of the utmost value in allowing us to study what happens to ureters after they have been resected and reimplanted either into the bladder itself or into the bowel. This is a question that has been crying out for solution for many years and it is likely now to be solved for all practical purposes.

FUNCTIONAL AND DYNAMIC TESTS.

1. It seems probable that the comparative *functional value of each kidney* can be estimated by observing the time and density of the appearance and disappearance of the X ray shadows. The quicker and more densely the shadow appears and the quicker it fades the better the kidney. If a kidney is slow to excrete the drug or if a shadow does not appear at all on one side this suggests more or less severe loss of function or even absence of the kidney. Inflammation and tumour formation delay or even prevent excretion. Back pressure delays but does not prevent excretion. In some cases the loss of function has been shown to be temporary, as for instance in cases of calculous anuria or of toxic or bacterial nephritis. A failure on a single occasion to observe a shadow should not lead to the conclusion that one kidney is completely destroyed or absent. The examination may have to be repeated.

2. The method can be used as a means of estimating the *power of both kidneys* together, either by precipitating the urine passed in a given time with strong acid and securing a measurable amount of dried uroselectan, or more simply by estimating the specific gravity of the urine passed every half hour after the injection. Normal kidneys seem to be able to excrete about three-fifths of the substance during the first two hours after injection and about another quarter in the next hour. After that, though some of the substance is still being excreted, it is not in a high enough concentration as to throw a shadow on the plate; 90 to 95 per cent. of the substance can be recovered from the urine unchanged in six to eight hours.

The specific gravity of the urine in the case of healthy kidneys may rise rapidly to about 1030 in an hour and even to as high as 1050 in less than two hours. Then it begins to sink rapidly again to its normal level. These rates of rise of the specific gravity can be compared with the density of the X ray shadows. Our experience so far has been that this rise in specific gravity is not always seen in some cases where the kidneys do not appear to be depressed in function. It is doubtful if this test is of universal application.

3. *Dynamic Tests.*—Roseno made some observations of interest on the tone of the muscle of the pelvis and ureter in cases of pyelitis of pregnancy, and in cases of stone in the ureter. For instance, his observations suggest that in cases of loss of tone forced drinking of fluid may lead to undesirable stretching of the ureter and may be a cause of renal pain. Observations similar to the method of pyeloscopy elaborated by Legueu are being carried out by von Lichtenberg, and it is hoped that they may lead to an even fuller knowledge of the dynamics of the ureter, since the ureter is not being disturbed or obstructed by the presence of a ureteric catheter. Now is not the time to speak further of these observations but it is highly probable that they will prove of importance.

Diagnosis and Treatment.

Owing to these dynamic alterations of the ureter the interpretations of the X ray pictures are often very difficult and mistakes are easily made. The pictures cannot be interpreted by the canons of ordinary urography. For instance, the musculature of the pelvis itself may be in spasm, in which case curious outlines appear that might at first sight suggest filling defects. At other times the musculature is in a state of temporary atony. If this appearance is mistaken for permanent atony operation may easily be advocated and carried out in cases where it is not needed. Again, the ureter often fails to show up in its entire length. In one picture the upper part of the ureter is seen, in another only the lower part. This simply means that a picture of a wave of normal peristalsis has been caught by the photograph. In other cases the ureter may appear to be dilated without physical obstruction, or it may be dilated in part only, or above or below an obstruction. The reading of the true meaning of this dilatation is difficult and varies with each case. In some the dilatation is a temporary atony. In others a permanent dilatation due to obstruction or inflammation. Each photograph can only be read by considering all the other features of the particular case. The biggest trap of all seems to be the difficulty of distinguishing between a tumour of the kidney and a kidney temporarily out of action from inflammation.

In the early days of bacteriology and biochemistry the true progress of clinical medicine received a check as enthusiastic observers attempted to make a so-called diagnosis by means of bacterial or chemical tests alone. The patient was apt to be forgotten and his interests suffered. The same thing is likely to happen in the first rush of enthusiasm to use uroselectan. Even if the drug is found to furnish anatomical and functional evidence of value in 50 to 70 per cent. of all cases examined, yet the facts so obtained will never be sufficient to yield a diagnosis in the true sense of the word. Such a diagnosis can best be made by men long trained in the clinical application of all the diagnostic methods available. Even more important than the diagnosis is the provision of sound advice as regards prognosis and treatment. Uroselectan will fail to be of benefit if this is forgotten.

CALCULI.

We may take as an example cases of stone. Even to-day few seem to be aware that in a large proportion of cases where a stone is detected by X ray examination *no operative interference is required.* At least 80 per cent. of ureteric stones can be removed by cystoscopic methods, and open operations for the

removal of these stones in the hands of urologists are seldom employed. Again, for reasons well known to the specialist, it is often highly undesirable to operate on patients with large bilateral renal calculi. The question of the need for removal of large unilateral stones or of smaller stones in one or both kidneys is one that requires long experience. It is surprising how many can be left alone with advantage to the patient. Even if operation is considered necessary, large issues depend on the type of operation employed whether it is to be pyelolithotomy or nephro-lithotomy or a combination of both, whether the kidney is to be drained and washed out afterwards, or whether the kidney is to be removed altogether. Unless such an operation is performed by a surgeon who has made a special study of the subject recurrence of the stone within a year is the common result, and the kidney is often very much damaged by the operation. As regards stones in the bladder, the common failure to make use of litholapaxy or of prostatectomy proves that often those who operate on these cases at the present day by means of cystotomy do not understand the first principles of the subject. There is no need to labour this aspect of the subject further. Suffice it to say that uroselectan is bound to help the urologist in carefully picked cases. It seems probable that better substances will shortly be discovered now that it is realised that excretion-urography is a practical proposition.

INTRAVENOUS PYELOGRAPHY

AS A TEST OF RENAL FUNCTION.

BY KENNETH HERITAGE, M.B.LOND., F.R.C.S.ENG.,
LATE RESIDENT MEDICAL OFFICER, MILLER GENERAL HOSPITAL.

INTRAVENOUS urography fulfils a long-felt want, not only in revealing morphological changes, but in giving a clue to functional capacity. My brief experience leads me to think that the time of appearance rather than the density of the shadow is the real test of renal function. In all cases in which the drug has appeared in under half an hour Mr. R. Ogier Ward and I [1] have found a good deal of macroscopically normal renal tissue. The ability to excrete uroselectan, in sufficient quantity to be detected radiologically, seems to be retained although the organ may be working under difficulties, and in cases in which the pelvic shadow has been absent from all radiograms, and where we have had the opportunity of confirming our findings either at operation or autopsy, we have found the organ so completely disorganised as to be obviously functionless. In normal cases, and in any other cases where obstruction was absent, a difficulty has been that the radio-opaque urine is evacuated into the bladder as fast as it is excreted. Thus it is not unusual in a normal case to find, a quarter to half an hour after the injection, that the pelves and ureters are only very faintly outlined, whereas the shadow of the bladder fills the pelvis.

In most of these cases pyelography has been undertaken to exclude early renal disease, and while it is of value to know that the renal function is normal, and that there is no obstruction to emptying a satisfactory outline of the pelves *and calyces* must be obtained. It seems possible to overcome this difficulty by temporary compression of the ureters. We have noted that using the method of J. Ziegler and H. Köhler it was possible to obtain an outline of the renal pelvis after the administration of sodium iodide and urea by the mouth. The prolonged compression (the above workers recommend half an hour) is not without disadvantage and possible risk. It has been shown experimentally that prolonged ureteric obstruction makes a kidney more liable to blood-borne *Bacillus coli* infection. At first we attempted to obstruct the ureter by an occluded ureteric catheter. The urine, however, drained away alongside the instrument and no contrast filling was obtained. Using uroselectan, ureteric compression of a few moments, certainly not more than five minutes, was sufficient to outline the calyces in cases with no marked depression of function.

The routine recommended is to observe the time of appearance of the drug in the quarter and half-hour films; if a shadow has appeared by this time demonstrating satisfactory renal function, but the calyces fail to show although the bladder shadow shows well, compression is applied to the ureters at the level of the sacroiliac joints. The compression required is not great. A pad similar to that used for renal compression may be applied by a special arm attached to the X ray couch, or an inflatable rubber bag may be held in place by a webbing belt. In practice we have found the latter method quite sufficient.[2] Anything approaching anatomical occlusion of the ureteric lumen is not attained; merely a hindering of peristalsis is sufficient. In the very stout this method is useless, so it seems that cystoscopic pyelography must be added to the already considerable penalties of obesity. Even in patients of average build, a high standard of radiological technique is often required to show the faint half-shadow of a rapidly emptying normal renal pelvis and it is probable that on a poor film no shadow would be seen at all. In such, and also in cases with poor function, a brief compression of the ureter may serve for distinction from cases of absent or functionless kidney.

Intravenous pyelography is the complement of cystoscopy, but its use must be combined with and its results checked by, the older urological methods. The indiscriminate employment of uroselectan as a short-cut to urinary diagnosis cannot but be condemned.

[1] See Brit. Med. Jour., 1930, i., 734.

[2] Mr. Schranz of the Genito-Urinary Manufacturing Co., has made for me an abdominal belt incorporating an inflatable rubber bag for ureteric compression.

WEST OF SCOTLAND RADIUM CENTRE.—Early this year the Western Infirmary of Glasgow was selected as the national radium centre for the West of Scotland. It has now received its first consignment and the amount available is about one gramme. The national radium will be used only in the hospital, but no such restriction is attached to the radium purchased two years ago with £5000 given by Sir Henry and Lady Mechan. The Glasgow and West of Scotland Radium Committee at Glasgow University has for several years possessed 700 mg. which furnishes radium emanation for five of the principal hospitals of the city. In 1928 the Glasgow Royal Cancer Hospital increased its supply with £10,000 given for the purpose by Lady Constance Burrell.

TELLURIUM IN THE TREATMENT OF SYPHILIS.

By A. D. Frazer, M.B. Edin.,
VENEREAL DISEASES OFFICER, COUNTY BOROUGH OF DUDLEY.

Levaditi,[1] alone and in collaboration, has investigated the value of tellurium in experimental rabbit syphilis and spirochætosis. Out of numerous preparations the best were a suspension of tellurium element in glucose and of tellurium oxide or tellurium iodo-quinine in oil. All three had a powerful prophylactic action. A dose of a fortieth to a tenth of a gramme per kilogramme body-weight, injected intramuscularly 8 to 27 days before inoculation of syphilitic material, would prevent a rabbit contracting the disease, and would continue to do so for something under 108 days in the case of the smaller dose and for over 116 days in the case of the larger dose. It was found that the tellurium in the tissues must reach a certain minimal quantity to prevent infection, the "potential métallique tissulaire" of Levaditi. Thus animals which had resisted infection with *Spirochæta pallida* up to 172 days after injection of tellurium showed at least 0·8 to 1·0 mg. of tellurium per gramme of dried renal substance on autopsy. The corresponding figure in animals successfully infected was 0·49 mg. per gramme. Curative experiments were similarly successful.

Absorption.

A section through the site of inoculation showed a central zone where the tellurium persisted for weeks or months as acid crystals or amorphous granules; the time depended on the form of drug used, the element remaining the longest. This central zone was surrounded by a layer of polymorphonuclear leucocytes and muscular fibres injured by the coagulation necrosis, with small needles of tellurium lying between the fibres; yet further out lay reaction tissue composed of new vessels, muscle-fibres, and many mononuclear leucocytes.

Tellurium was found generally throughout the body, but only two parts are of special interest.

The basal part of the *intestinal glandular epithelium* showed the drug lying surrounded by mononuclear leucocytes and elimination by the mucosa is thought to be preceded by an accumulation of tellurium in the cytoplasm of these surrounding cells. The *kidney* showed a slate-coloured cortex, but the medulla appeared healthy. On section the epithelium of the convoluted tubules and the intermediate portion of the ascending loop of Henle was found to be literally packed with tellurium "granulations," while they were very rare in the glomeruli or the tubes of Bellini.

"Granulations" are composed of grains of tellurium, ½–1 μ long, fixed in the excretory cells. Water, by its oxidising power, shows a distinct difference between tellurium injected into muscle and tellurium as found in the renal cells. The former resists water for a long time; the latter is quickly oxidised and easily soluble. The former is insoluble in lipoid solvents, and thus is precipitated by alcohol from the kidney, and in this way a rich watery extract, which is non-dialysable, may be made.

The action of the metal on the spirochæte in vivo became apparent on the second day, being shown by irregularity of the spirals and the appearance of lumps and terminal granules. Later, phagocytosis occurred. The spirochætes most affected were phagocytosed first, and were fixed most easily by silver.

In Levaditi's opinion, injected tellurium becomes soluble by combining with tissue protein to form a complex proteo-metallic substance dissimilar to the original element. The mononuclears, apparently by their mitochondria, assimilate this and reduce it as a means of defence against the toxicity of the soluble tellurium derivative.

Clinical Studies.

Fournier and others [2] have tried various preparations of tellurium in the treatment of human syphilis. The element itself, the oxide (TeO_2) and the iodo-quinine gave the most promising results. In early cases the spirochætes disappeared by the second, third, or fifth day after administration; the chancre cicatrised rapidly and the glands receded. In florid syphilis the rash quickly faded, and the flocculation test or Wassermann reaction became negative. Subjective improvement and a tonic effect on the general health was obtained in two cases of central nervous system involvement. In this series 14 cases were treated with tellurium alone. One case was resistant, and did not improve, and one relapsed after treatment was stopped; all the others reacted successfully. No toxic effects were found, except a constant odour of garlic in the breath and in some cases a bluish discoloration of the skin, especially where it was exposed to the sun.

The route chosen was the intramuscular in all cases.

WASSERMANN-FAST CASES.

It is evident that tellurium is a powerful anti-syphilitic drug which would undoubtedly be more widely used but for the inevitable smell of garlic following its administration, and the fact that bismuth seems to act almost identically without producing this odour. There remains, however, one class of case in which tellurium might be useful—namely, the Wassermann-fast case, where, in spite of the exhibition of arsenic and bismuth or mercury, the patient does not react serologically and lives with the possibility of recurrence of clinical manifestations of the disease hanging over his head. Tellurium has not, as far as I know, been tried in this type of case. Seven patients were, therefore, selected and treated with the metal over varying periods of time.

A 5 per cent. suspension of the element in glucose was obtained* and tried first in the treatment of experimental *Spirochæta muris* infection in rats. It was hoped by this means to make an estimation of the probable spirochæticidal power, but unfortunately the drug showed very little activity against this infection, the results agreeing with the poor results obtained with gold and bismuth.[3] Patients were selected whose Wassermann test continued to give a positive result after intensive treatment with arsenic, bismuth, and mercury. A course consisted of about 5 c.cm. of tellurium suspension given intramuscularly in ½–1 c.cm. doses at intervals of 5–7 days. A month's rest was then allowed before the Wassermann reaction was tested. The details of the cases are as follows:—

Case 1.—Male, age 47. Date of infection unknown. Clinical condition syphilitic leucoplakia. Small doses given as general health poor. 2 g. neokharsivan and 2 g. bismuth in eight weeks. Developed jaundice. 14 g. bismuth only administered in next 12 months, followed by a course of 2 g. neokharsivan and 2 g. bismuth. Total of 4 g. neokharsivan and 18 g. bismuth in 17 months. Wassermann reaction always strong positive.

2·5 c.cm. tellurium given. Wassermann reaction negative, relapsing to doubtful negative in eight weeks, and to weak positive in six months.

Case 2.—Male, age 64. Infected 40 years previously. Clinical condition syphilitic leucoplakia. During second course of treatment with neokharsivan and bismuth a dermatitis developed. Arsenic stopped and bismuth

*Kindly supplied by Burroughs Wellcome and Co.

continued in small doses. Total 5 g. neokharsivan and 12 g. bismuth in one year. Wassermann reaction always strong positive.

Given 5·5 c.cm. tellurium. Wassermann reaction doubtful negative. Treatment with bismuth was restarted, but the Wassermann reaction relapsed to weak positive in five months. Still weak positive nine months later.

CASE 3.—Male, age 47. Infected 20 years previously. Clinical condition syphilitic hemiplegia. Received large quantities of various "606" and "914" preparations, intravenously and intramuscularly, including silver salvarsan, sulfoxyl salvarsan, sulfarsenol, &c., also bismuth and mercury over a period of six years. Wassermann reaction varied between strong and weak positive. Given 6 c.cm. tellurium. Wassermann reaction negative. Ten weeks later still negative. Six months later weak positive.

CASE 4.—Male, age 59. Infected 20 years previously. Clinical condition syphilitic leucoplakia. Received 6 g. silver salvarsan, 8 g. "914," 25 grs. mercury, and 13 g. bismuth over a period of two years. Wassermann reaction varied between strong and weak positive. Given 5 c.cm. tellurium. Wassermann reaction negative but relapsed in one month to weak positive.

CASE 5.—Male, age 52. Infected four years previously. Wassermann found strong positive during routine examination. Treated for six years with "606," "914," mercury and bismuth. Wassermann reaction always strong positive. Given 8 c.cm. tellurium. Wassermann reaction unchanged.

CASE 6.—Male, age 62. Infected 26 years previously. Clinical condition gumma of sternum. Received 15 g. "914" and 25 g. bismuth during two years. Wassermann reaction always strong positive. Given 5 c.cm. tellurium. Wassermann reaction unchanged.

CASE 7.—Male, age 65. Infected 21 years previously. Clinical condition ulcerating gumma of leg. Received large quantities of various "606" and "914" preparations. also bismuth and mercury over a period of five years. Wassermann reaction strong positive. Given 4 c.cm. tellurium. Wassermann reaction unchanged.

CASE 8.—(This case will be discussed separately).—Male, age 25. Started treatment two years three months previously for chancre and strong positive Wassermann reaction. Wassermann reaction had been negative for one year when he reported with a history of coitus, a penile chancre swarming with *S. pallida*, and Wassermann reaction strong positive. Given 2·5 c.cm. tellurium. Wassermann reaction negative and has remained so under treatment with arsenic and bismuth.

TOXICITY OF TELLURIUM.

The toxicity of the drug in the doses given appears to be small. No emaciation or discoloration of the skin occurred in this series, although both have been reported elsewhere.[4 2] Perhaps a stronger sun than we can command in Edinburgh is required to produce the bluish discoloration described by Fournier. The most prominent side-effect is a smell of garlic. The drug is excreted as methyl telluride through the lungs and in the urine, and produces an odour which is constant, overwhelming, and extremely persistent. To counteract this, large doses of sodium thiosulphate were given orally and intravenously but with little effect. Strong-smelling orange mixtures did not influence it, and it was really this odour which made us give up the use of the drug. A faint smell would persist even 6–8 months after the last injection. It is said that workers in tellurium mines are affected in the same way but to a lesser degree.

Loss of hair pigment, due to tellurium has been reported, and this did occur in Case 8. A week or two after the first injection the hairs slowly grew white, not in patches but generally over the scalp. This persisted for about four months when the black hair reappeared, and by another four months no white could be seen. This is a rare manifestation of intolerance.

Discussion of Results.

The average age of the infection in the cases treated is nearly 19 years. This bears out the rule that the longer the duration of the disease the more firmly is it entrenched and the greater is the probability of a resistant infection developing. The cases in this series constituted a very severe test for any drug, and yet four cases out of the seven selected were influenced favourably by the tellurium preparation. In time the Wassermann reaction relapsed, although usually to a lesser degree of positivity than before this treatment. This was probably due to the fact that the quantity of tellurium in the tissues fell below the necessary level for therapeutic action. There is no reason to suppose that the Wassermann reaction would ever have returned to positive if more tellurium had been administered.

The smell of garlic is inextricably bound up with the excretion of the drug, and there seems to be no way of evading its presence or of alleviating its intensity. The other side-effects are rare, and in countries where the smell of garlic is not commented on, this drug should prove of great value. In special cases in our own country it may be the only means of affecting the Wassermann reaction.

One further possible use may be mentioned—namely, for prophylaxis. Case 8 was one of those cases with which we cannot deal satisfactorily under present conditions.

His unfortunate habits had resulted in gonococci being present continuously in his urethral secretion for almost two years. We can only surmise how many people he had infected in that time. When on a course of very small doses of neokharsivan, near the end of his treatment for syphilis he exposed himself to infection, and developed a penile chancre swarming with *S. pallida*. His blood, previously negative, showed a strong positive Wassermann reaction. We decided that tellurium was the most suitable drug. The administration of 2·5 c.cm. of the suspension made his blood Wassermann negative, and it has remained so under treatment with arsenic. It is interesting to note that at the same time gonococci disappeared from the urethral and prostatic secretions, with the result that he has at last been cured of his gonorrhœa.

Other cases of gonorrhœa were tried with tellurium without effect. The result in this case must be credited to the enveloping smell of garlic which effectually prevented exposure to infection for at least six months.

Summary.

Tellurium is active in rabbit and human syphilis. Seven Wassermann-fast cases were treated with tellurium, and four were favourably influenced. The toxic effects are small, but a smell of garlic is constant; this, however, should not prevent the use of tellurium in certain countries and in certain cases.

I wish to thank Mr. David Lees and Prof. T. J. Mackie for their advice and interest during the course of this study. The expenses for the work were defrayed by a grant from the Moray Fund.

CLINICAL AND LABORATORY NOTES

ADENITIS OF THE ILIAC GLANDS.

By R. J. McNeill Love, M.S. Lond., F.R.C.S. Eng.,
ASSISTANT SURGEON TO THE METROPOLITAN HOSPITAL.

Adenitis of the external iliac glands is a not uncommon surgical condition, and deserves wider recognition than it is usually accorded in text-books.

These glands are some 12 in number, and are arranged in three chains along the outer, middle, and inner aspects of the vessels; the lowest member of each chain lies close to the deep surface of Poupart's ligament, and together they form the retrofemoral group. The afferent vessels convey lymph from the deep femoral and some of the superficial inguinal glands, from the deep structures of the anterior abdominal wall below the umbilicus, from the bladder, and from the prostate, the uterus, and the upper part of the vagina. Thus a wide area is drained, but the commonest cause of inflammatory lesions is infection of the leg via the femoral group of glands.

As in other parts of the body, infection may "jump" one group of glands, and affect those more central; thus iliac adenitis may occur with no apparent inflammation of the inguinal glands. That it may be mistaken for a variety of conditions is illustrated by the following cases:—

Case 1.—A boy, aged 6, was admitted to hospital for immediate operation, on the assumption that he was suffering from acute infective arthritis of the hip joint, probably due to osteomyelitis of the neck of the femur. For three days he had complained of pain and stiffness in the hip, with increasing difficulty in walking. On examination he was obviously ill, with a temperature of 101·2° F., and a pulse-rate of 122. The right hip was rigidly flexed, and any attempt to increase flexion or to extend the joint was tearfully resented. A more detailed examination revealed a fixed, indurated, and tender swelling in the right iliac fossa, and rotatory movements of the hip could be obtained painlessly, thus disproving the diagnosis of acute arthritis, for which was substituted adenitis of the iliac glands with marked spasm of the psoas. No obvious source of infection could be discovered. The iliac swelling gradually increased in size; after six days an abscess was evacuated and recovery was uneventful. Staphylococci were the offending organisms.

Case 2.—A boy, aged 12, was admitted to hospital as suffering from an appendix abscess. Four days previously he had complained of abdominal discomfort which had increased and become localised to the right iliac fossa, and his doctor, on deep palpation, had discovered a tender swelling in that region. On admission the temperature was 100·4° F. and the pulse-rate 110, and on placing the boy prone it was found that extension of the right hip was limited as compared with the opposite side. Owing to the absence of more typical abdominal symptoms, a diagnosis of iliac adenitis was made, and this was supported by the presence of a chafed heel due to an ill-fitting shoe. Fomentations and symptomatic treatment were adopted, and the swelling gradually subsided and disappeared with attendant symptoms in about a fortnight.

Case 3.—A man, aged 39, stated that he had suffered for five days from left-sided abdominal discomfort, and increasing pain on walking, these symptoms becoming so distressing that he took to his bed and sent for his doctor, who found a tender swelling in the left iliac fossa and sent him to hospital with the diagnosis of diverticulitis with pericolic infection. On admission his temperature was 102·2° F., and his pulse-rate 108; a rounded painful swelling, the size of a large orange, was palpable above the left Poupart's ligament. Numerous infected gnat bites were present on both ankles. There was no previous history of any digestive disturbance. Two days later the swelling had increased in size, and was adherent to the abdominal wall immediately above Poupart's ligament. Half a pint of pus was evacuated, containing staphylococci, and recovery was uneventful.

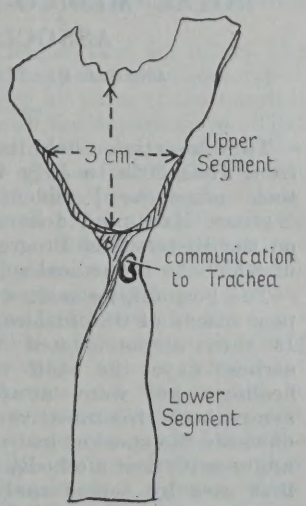
Adenitis of the iliac glands is, therefore, of surgical interest because of the possibility of mistaken diagnosis with the resultant risk of an unnecessary or injudicious operation. The gradual onset of symptoms, spasm of the psoas muscle, and often the presence of a focus of infection are all suggestive. Confusion with an appendix abscess may lead to evacuation through the peritoneal cavity, and consequent risk of peritonitis. If the condition is suspected or diagnosed, expectant treatment should be adopted, and if resolution does not occur, then the abscess should be opened through a small incision immediately above the outer part of Poupart's ligament, so that the pus can be evacuated extraperitoneally. Evacuation is facilitated by the fact that in all but small abscesses the peritoneum is already displaced upwards from the anterior abdominal wall.

CONGENITAL ATRESIA OF THE ŒSOPHAGUS.

By Cyril J. Polson, M.D. Birm., M.R.C.P. Lond.,
LECTURER IN PATHOLOGY, UNIVERSITY OF LEEDS.

Congenital atresia of the œsophagus is a rare condition, and an example, bearing a close resemblance to the four reported by Keith and Spicer [1] (1906), and that by Cooper [2] (1929), is now described.

A female child, aged 7 days, admitted to Prof. C. W. Vining's wards on May 24th on account of persistent vomiting which began on the 21st. It was born at full term and then weighed 7½ lb. When admitted it was a thin wasted baby weighing 4½ lb. The child became cyanosed when attempts were made to feed it, and all food was immediately returned; it was a hungry child. An œsophageal tube could not be passed more than one inch beyond the larynx. Death occurred on May 25th. At autopsy next day atresia of the œsophagus was found at the junction of its upper and middle thirds. The upper segment was dilated and hypertrophied, forming a wide pouch which had a smooth mucous lining; the lower was thin-walled and narrowed, but quite patent. There was a communication ⅛ in. in diameter between the upper end of the lower segment and the trachea at a point approximately ¼ in. above the bifurcation. There was a patent foramen ovale but no other congenital malformations.



Sketch of the œsophagus as seen laid open. The cut wall of the upper segment is shaded and indicates its thickness.

Keith and Spicer, when describing four similar cases, discussed the probable origin of this congenital malformation, and regarded it as a failure in the development of the tracheo-œsophageal septum.

[1] Keith, A., and Spicer, J. E.: Jour. Anat. and Phys., 1906-07 xli., 52.
[2] Cooper, T. V.: The Lancet, 1929, ii., 607.

They mentioned that Morell Mackenzie collected 63 cases, but had seen only one of them himself. The present case is the first amongst a series of 12,000 autopsies at the Leeds General Infirmary.

I wish to thank Prof. Vining for permission to use the clinical notes of this case.

CULTIVATION OF A TUBERCULOUS GRANULOMA IN VITRO.

BY THOMAS LUMSDEN, M.D. ABERD.,
DIRECTOR OF THE CANCER RESEARCH LABORATORY, LONDON HOSPITAL.

DURING routine cultivation of a series of human neoplasms small fragments of a tuberculous mass arising from the spinous process of a dorsal vertebra, kindly supplied to me by Mr. Robert Milne, were cultured in the serum of the patient, a boy 8 years of age. After 24 hours endothelial cells migrated out freely from the original fragment forming an irregular network around it. The cultures were re-fed with the serum every four to five days, and were still alive a month after removal from the body.

It was observed that the migrating cells were of three varieties: (1) Lymphocytes which disappeared after a week's cultivation. (2) Endothelial ("epithelioid") cells. (3) Fibroblasts. The chief interest attached to the endothelial cells. Some of these divided after their emigration; others, which could be individually recognised, survived without division during the whole month. Of the latter several gradually enlarged and their nuclei divided, probably amitotically, so that five or six nuclei coexisted in a single cell. These cells resembled the giant cells which occur *in corpore* and as in them the nuclei tended to locate themselves at the periphery of the cytoplasm. In certain instances some of the nuclei migrated out from these giant cells with some attendant cytoplasm but remained attached to the parent giant cell by fine strands, giving very much the appearance familiar in microscopical sections of a miliary tubercle.

It appears therefore that, at least under the artificial conditions inseparable from tissue culture, giant cells are formed, not by the fusion of cells originally separate, but by repeated nuclear division without coincident division of the cell cytoplasm. The observed facts suggest that in the formation, under the stimulus of tuberculous infection, of a miliary tubercle, a single endothelial cell transforms itself as above described into a giant cell. This throws off from its circumference an encircling and adherent group of separate mononuclear endothelial cells. Lymphocytes, which are probably protective in purpose, accumulate from the blood stream, completing the characteristic picture.

MEDICAL SOCIETIES

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

ANNUAL MEETING AT OXFORD.

THIS Association held its annual meeting at Oxford from June 30th to July 4th. Dr. T. SAXTY GOOD took office as President, in succession to Dr. NATHAN RAW, and delivered a presidential address on the History and Progress of Littlemore Hospital, of which he is medical superintendent.

The hospital, he said, was opened in 1847 for the poor insane of Oxfordshire, Abingdon, and Berkshire. It then accommodated 134 patients. From the earliest days the staff were interested in mental healing and were aware that occupation and sympathetic treatment were essential. From 1911 onwards the speaker had made tentative attempts to apply analytical methods, and in 1915 he treated his first case by actual analysis. During the war, in company with Prof. William McDougall, he began to treat out-patient cases from surrounding camps, and this had led to the foundation of the out-patient clinic for nervous disorders at the Radcliffe Infirmary. In 1918 Littlemore was taken over by the War Office under the name of Ashhurst Hospital. During the war period hypnosis was much used, but since then it had been found less and less valuable while ordinary analysis was increasingly employed. In 1922 Littlemore was reopened as a mental hospital. War experience had shown the importance of the open-door system, and structural alterations were made accordingly. Windows were lowered, bars removed, wards made larger, and single rooms reduced in number. The results were admirable. Nurses were now trained in handicrafts so as to encourage the patients to imitate them, and an interchange of nurses between Littlemore Hospital and the Radcliffe Infirmary was proving very useful.

The outstanding features of care and treatment at the hospital the president summarised as follows: (1) the open-door system; (2) new patients are always told where they are and why they have been sent to the hospital; (3) all delusions and hallucinations are discussed with them; (4) they are always listened to, and their remarks are investigated; (5) they are always told when they are to be moved to another ward, and why; (6) the general rule of the hospital is to try all methods, both physical and psychological.

Mental Changes in Cardiac Disease.

Dr. A. G. GIBSON said that the results of cardiac deficiency need not be limited to its effects on the circulation in the brain, for there might be secondary effects from changes in the glands and other organs disturbed. Pericarditis in children sometimes caused querulousness and neurasthenia, and angina pectoris patients were often emotionally unstable. Children having cardiac failure in association with diphtheria were acutely conscious of approaching death until the final stupor. Aortic regurgitation, especially the syphilitic variety, might be associated with impulsive insanity. In people of advanced age Clouston observed a cyanotic delirium and cyanotic insanity due to lack of oxygenation of the blood; it was seen in bronchitis, cardiac disease, and asthma. Carey Coombs, reviewing 2000 cases of cardiac disease, could not find support for the view that cardiac disease in itself was responsible for mental disease, for he found only ten cases of insanity associated with rheumatic heart disease. Riesman, on the other hand, said that cardiac patients were often depressed and irritable, and that, especially if aortic disease was present, there were frequently

hallucinations of sight and smell. Some showed acute mania which defied control.

Dr. Gibson had found that patients with gross cardiac failure might show no mental change beyond a gradual enfeeblement of the mind. He had analysed the 153 of his cardiac cases in which there were mental symptoms, with the following result. In mitral stenosis 16 per cent. had mental change, in fatty infiltration 15·3 per cent., and various other conditions gave 6·1 per cent. of altered mentality. Mitral stenosis and ischæmic necrosis seemed more likely than other cardiac lesions to cause mental symptoms. When these were due to cardiac disease or faulty action, they rapidly improved if the heart's activity could be restored to the normal. A danger lay in wrongful certification when physical examination was omitted.

Sir HUMPHRY ROLLESTON pointed out that mental disorder in cardiac failure might be due to conditions classed as uræmic. In some cases, loss of mental balance might be attributable to treatment —e.g., by salicylates. In ischæmic necrosis the mental condition was, perhaps, due to the rapid fall of blood pressure.

Prof. WALTHER SPIELMEYER (Munich) read a paper on the Influence of Functional Circulatory Disturbances on the Central Nervous System. He spoke of changes in which there was no apparent change in the vessel wall or in the lumen, but which nevertheless caused functional disturbance.

Sedatives of the Central Nervous System.

Prof. J. A. GUNN said that drugs produced their action by a chemical interaction with the tissues, and as the chemistry of muscle differed from that of nerve, their selective action could well be understood. It was not yet known what was the chemical basis for this selective action, but considering, for instance, the extraordinary complexity of the cell and the complexity of such a molecule as that of strychnine, it was not surprising that the drug should pick out one cell in preference to another. The simpler the molecule, the less selective action was likely to be exerted. Though no chemical reason could be given for the selection exerted by certain drugs, much valuable knowledge had been derived from careful observation of their effects, especially the order or rotation in which they affected various tissues. Prof. Gunn urged that those employing sedatives should furnish exact records of their effects; every small fact was important. Some people had the idea that because a small dose of a drug sufficed, it was therefore a safer drug, but the contrary was true.

Psychotherapy at Out-patient Clinics.

Prof. GEORGE M. ROBERTSON pleaded for the extension of out-patient mental clinics. Many believed that every mental hospital should have a clinic or clinics connected with it, and with the Mental Treatment Act becoming operative this became a duty. Formerly the interest of the mental hospital medical officer started with the entry of the patient into the institution after his certification, and ended when he was restored to his family on discharge. This implied a lack of experience and understanding on the onset of mental disease, and of preventive treatment. Clinics brought the medical officer into closer contact with the domestic life of the poor, and this closer touch must dispose of much of the suspicion usually attaching to the treatment of mental disease, at the same time bringing the mental hospital doctor into a better appreciation of the problems of general practice.

Clinics tapped a large field of minor mental ailments which caused great suffering, but often received scant attention even from the practitioner, who merely regarded such patients as troublesome. Children were brought who were backward at school, who had been difficult to manage, or who on account of minor delinquencies had been difficult to manage at home. The best form of out-patient mental clinic was that attached to a general hospital, for a patient at such an institution had little hesitation in asking for advice on nervous symptoms, and there was the further advantage of a specialist staff and a laboratory. The clinic should be in charge of an experienced psychiatrist, and there should be coöperation with the neurologists of the hospital. Another method was to have the clinic in association with a mental hospital. This had the disadvantage that people were shy or afraid of approaching a mental hospital, but in various ways the difficulty could be minimised. As most mental hospitals were built in the country and were at some distance from centres of population, a mental clinic must be opened in the nearest large town, and, if possible, in connexion with the local hospital. As a supplement to the clinic there should be one or more social workers who should take notes when the patient was being examined and, if necessary, visit the patient's home and make discreet observations and inquiries. She should also try to ascertain whether the treatment was or could be carried out.

The object was to try to treat mental ailments at as early a stage as possible, and under the Mental Treatment Act it was possible to treat cases of mild melancholia in these clinics. He thought that the passing of the Act to admit voluntary patients to county mental hospitals should be signalised by the opening of out-patient clinics by the medical officers of these hospitals, so as to crown the benefits conferred by the Act.

Dr. WILLIAM BROWN hoped that in future the hospital managements would appoint a psychotherapist who should be in touch with all parts of the hospital and receive patients from all the departments. That meant education as to the needs, and it was a slow process. Many members of hospital staffs did not know the possibilities of the psychological side. Even in such a matter as the preparation of patients mentally for undergoing a surgical operation the psychotherapist had a real place. Accurate diagnosis and great discrimination were needed before psychoanalysis was embarked upon. He thought there was a danger of the possibilities of suggestion being neglected. Deep analysis could not be carried out in less than 50 to 60 hours, and that would be impossible in a mental out-patient clinic, but this did not mean that analysis would be neglected in the clinics. On the knowledge derived from complete analyses, much could be done in short séances. Moreover, in some cases it was useless and a waste of time to do much analysis, because the patient withheld important facts.

Dr. HUGH CRICHTON-MILLER thought all needed to have their eyes opened to the minor mental maladies of life. That they were very rife was shown by the number of attempts at suicide by people whose trouble was unsuspected. A clinic for dealing with these maladies could serve a great purpose, whether in association with a general or a mental hospital or an independent clinic. Much could be said for each system. Some advocated the establishment of clinics in association with the educational and scholastic system, an idea which was far from absurd. It must always be realised that each case required a great deal of time for treatment. There seemed to

be an impression that, provided a council gave a site and a grant for a suitable building, and someone gave leave to the staff of a local hospital to run it, everything for an out-patient mental clinic had been provided for. But, unless there was a positive therapeutic ideal, it was better not to ask county councils to put up clinics. At the Tavistock Clinic no one without adequate personal experience of analysis was allowed to use suggestion. After considerable experience it was found that each patient required on the average about 12 hours' attention.

Dr. HENRY YELLOWLEES referred to the admirable out-patient mental clinic in association with the Wakefield Mental Hospital, which under the new Act would probably be more valuable still. He said that the clinic established in connexion with the general hospital at York had had greater success after its name was changed from "clinic for functional nerve disorders" to "mental out-patients clinic." Sometimes an absurdly small amount of psychotherapeutical treatment brought a result which was marvellous to the patient.

Dr. R. D. GILLESPIE said it seemed that there were something like 3,000,000 cases of mental disorder in this country. At Guy's Hospital 75 per cent. of the children he saw either got well or were considerably improved, a figure nearly twice as good as in adults. He believed that if congenial occupations were found for those leaving school, possible breakdown later would be largely prevented.

Mr. L. G. BROCK said it might be worth while to try to get mental and general hospitals to jointly organise a travelling clinic, which should come within the reach of all potential patients. He looked forward to the time when besides the public mental hospitals there would be in all teaching hospitals and, he hoped, in the larger non-teaching hospitals too, a psychopathic unit, or at least wards for mental cases.

Dr. R. A. NOBLE said that in Australia the problem of out-patient treatment of mental cases had been widely and satisfactorily tackled. Success depended largely on the personality of the workers.

Dr. D. SLIGHT emphasised the need for psychiatrists taking a general medical viewpoint. In McGill University psychiatry was taught not as a special subject so much as a general approach to medicine.

Personal Communications.

Dr. G. F. PETERS read a paper on the Therapeutic Effect of Assisted Respiration in Established Cases of Dementia Præcox. It had been suggested, he said, that it might be profitable to explore a line of treatment based on the elimination of carbon dioxide without increasing the patient's acidity. With this object female patients at the Horton Mental Hospital suffering from dementia præcox had been treated by assisted respiration—i.e., Sylvester's method of artificial respiration, with modifications, was carried out for 15 minutes daily. After every five respirations a pause was observed, during which normal respiration was resumed. As volition increased, breathing exercises were introduced; dancing and skipping were also used. With the exercises tasks were introduced, at first those connected with personal hygiene. Of 12 cases so dealt with four showed moderate improvement, which had been well maintained for six months. Six showed slight yet definite improvement. The improvement was chiefly on the conative aspect. Two of the cases who failed to improve were so ill that from the first they might have been considered hopeless. The treatment seemed to provide the first step towards re-establishing contact with social activity. It had been necessary to use to the best advantage in the process of re-education the knowledge of the patient's previous history.

Dr. D. K. HENDERSON and Miss S. MACLACHLAN read a paper describing two cases of Alzheimer's disease with post-mortem findings on fatal cases.

In one typical case, that of a woman aged 51, there was a gradual failure of mental power; the patient became suspicious and jealous, was perplexed and disorientated for both time and place, and experienced difficulty in expressing her thoughts. She was ill 4½ years, and shortly before death she had contractures. At post-mortem a striking alteration was found in the neurofibrils. In an otherwise normal cell there appeared at first one or more fibrils, and these stood out prominently. Many neighbouring fibrils were similarly affected, and these formed bundles, which gradually came to the surface of the cell, and nucleus and cell disintegrated. Throughout the cortex were found many similar foci or plaques.

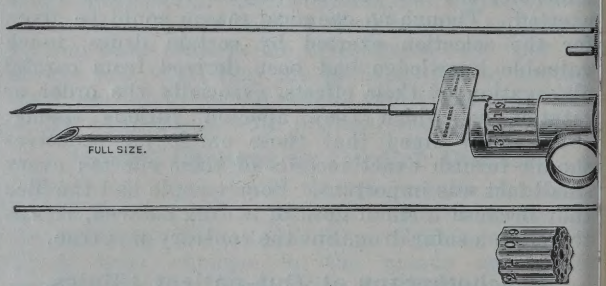
The cases must be distinguished from ordinary senile mental disease. British literature contained very little reference to the condition.

Prof. C. G. SELIGMANN read a paper on Temperament and Insanity in the Far East. He pointed out that while the virus of a disease might be much the same its manifestations were modified by peculiarities of environment, temperament, and habit. Hysteria was common among the Chinese, and they were very suggestible; 30 per cent. of the asylum population in Japan had general paralysis of the insane.

NEW INVENTIONS

RADON SEED INTRODUCER.

THE introduction of large numbers of radon seeds into the tissues with the ordinary trocar and cannula is a somewhat tedious process, and I have therefore designed a magazine introducer shown in the illustration with a detachable magazine carrying ten



seeds. The introducer is held in the left hand, and the magazine is rotated by the thumb, while the plunger is pushed in with the right hand. In this way ten seeds can be pushed home with great rapidity, whilst they can be planted in rows with remarkable accuracy, the cannula being withdrawn a centimetre or so after the introduction of each seed. The saving of time is considerable, but perhaps even more important is the gain in precision in the distribution of seeds. The original instrument was made in my own workshop at the London Hospital, and its use over a period of several months has convinced me of its great convenience.

The instrument is now being manufactured by Messrs. Down Bros., of St. Thomas's-street, Borough, London, S.E.

H. S. SOUTTAR, F.R.C.S. Eng.

REVIEWS AND NOTICES OF BOOKS

Insects, Ticks, Mites, and Venomous Animals of Medical and Veterinary Importance.

Part I.: Medical. By WALTER SCOTT PATTON, M.B., Ch.B. Edin., F.E.S., Dutton Memorial Professor of Entomology, Liverpool University and Liverpool School of Tropical Medicine; and ALWEN M. EVANS, D.Sc., Lecturer on Entomology in the School of Tropical Medicine. Privately published. Pp. 786. 20*s*.

THE size of this book is accounted for by its design; the authors, finding no comprehensive treatise, either of a theoretical or practical nature, dealing with the insects and acari which are of importance from the medical standpoint, have decided to fill the gap. This they are well qualified to do as, to quote Prof. Newstead's foreword, "Both have laboured in the fields of medical and veterinary science for many years, and both are highly distinguished experts in their subjects of which they treat."

The volume under review is the first of four; it deals with the medical and veterinary aspects of entomology, and is planned to meet the needs of candidates for the diploma in tropical medicine in the University of Liverpool; this is the first objective, but the information will be equally valuable to those who aspire to cognate diplomas at other university centres. Further, no intending examinee before any qualifying body can possibly require one-tenth of the information supplied. For the authors have purposely written, at the same time, with that large and important section of the profession in their eye, who, as medical officers of health, have obtained already a special diploma but require to have by them, for their instruction, a text-book in which they will find not only the information which they had mastered formerly for the purposes of examination but also a practical guide to their future work. It is intended that the work should not be used as a cram book for a particular examination, but should be of continuous utility as a contribution to the whole subject. Therefore particular stress is laid on morphology, without a knowledge of which it is not possible either to recognise the various insects, when to do so may be of the first importance in preventive medicine, or, indeed, to take an intelligent interest in their pathological rôles.

The all-round nature of the book, which accounts both for its size and its profuse illustration, is indicated in a synopsis of the preliminary lecture in the course given to the Liverpool students. In this lecture will be found what amounts to an introductory résumé of the contents of the book. A classification is given of the parasites and their carriers with which familiarity is expected, and that classification, which extends over 36 pages, is accompanied by really beautiful illustrations. The insects which form one of the most important classes, the *Phylum arthropoda*, include 500,000 individuals which have been described, and probably half as many again remain to be discovered. Of this vast population a large number will be found fully set out, their portraits, mainly by Mrs. Patton, accompanying the text. The instruction given by a good drawing of a specimen or insect can hardly be exaggerated, and for it to be of full value it is necessary that the various parts displayed should be easily recognisable by lettered descriptions. A feature of many of these illustrations is the elaborate lettering of the drawings for which Miss M. Brown is responsible. The numerous drawings of mosquitoes are by Mr. A. J. Engel Terzi, whose assistance to medicine in this direction is familiar.

It is proper to note that this work replaces Patton and Cragg's "Text-book of Medical Entomology," which is now out of date and out of print. That book was published 16 years ago and remains to-day the only comprehensive treatise on the subject. The present volume has been published privately and is sold at a price within the reach of all to whom it may be of use. The volume can only be obtained from the Entomological Department, Liverpool School of Tropical Medicine, and any number of copies can be sent. The extraordinarily low price, 20*s*., includes packing and postage to any destination, and all copies going to the United States will contain an invoice for Customs purposes.

Uniform with this volume, Part 2 on Public Health, Part 3 on Tropical Hygiene, and Part 4 on Veterinary Medicine, in relation to entomology, are announced for early issue.

The Diagnosis of Health.

By WILLIAM R. P. EMERSON, M.D., Medical Consultant in Physical Fitness at Dartmouth College, U.S.A. London: D. Appleton and Company. 1930. Pp. 272. 10*s*. 6*d*.

WE commend this book most heartily to the promoters and organisers of societies for the maintenance of health, especially to those whose propaganda is based upon too facile hypotheses. By such apostles—those who impose shallow views upon the public as being the secret for the eradication of disease—this book should certainly be studied; for if they have themselves taken the trouble to do the work involved in grading various states of health, constructing endless weight tables, making "personality examinations," and deducing "health intelligence quotients," based upon examination and interrogation of a very complicated nature, they will be able to compare American methods and results with their own. If, on the other hand, they have been content merely to bask in beautiful health dreams, they may be stimulated as they read to begin to get down to physical facts and to join in the search for truth—in short, to do some work.

To the physician whose professional time is mostly occupied with practical details in diagnosis and treatment of sick persons the book will make but slight appeal. He will be inclined to doubt whether health can be numerically assessed in percentages and quotients; and even whether the elusive personal equation in each case can be solved by analysis of the patient's personality into 17 component parts, such as reliability, sportsmanship, care of own and other's property, and coöperation, as enumerated in Chapter VIII. Moreover, it is quite likely that physicians might feel that principles of safety first, which must be the primary motive of Dr. Emerson's wide researches, would tend to direct the attention of normal persons too much towards standardising their health at the expense of their civic and cultural development. However, in so far as the book is founded on carefully ascertained facts and not on theory, it must command the respect of all interested in hygiene. Whether the aberrations from the averages constituting "optimum health," in Dr. Emerson's phrase, are properly regarded as physiological variations, or as danger signals on the border-

line between health and disease, will depend upon every man's individual perspective. But his method of study is conscientious, and it may lead to valuable knowledge.

Les régimes du nourrisson.

By E. LESNE and ROBERT CLEMENT (l'Hôpital Trousseau). Paris: Gauthier-Villars et Cie. 1930. Pp. 172. Fr.25.

THIS book consists of two parts, one dealing with the diet of normal infants and the factors concerned with growth, and the other with the feeding of sick infants. A clear account is given of the underlying principles of infant feeding, but in the chapter on artificial feeding with fresh milk the process of simplification has been carried too far, milk modification being dismissed in a few lines. The various methods which are used in the feeding of infants suffering from marasmus and other alimentary disturbances are more fully discussed. Considerable attention is paid throughout the book to the quantitative aspect of infant feeding.

Journal of Pathology and Bacteriology.

Vol. xxxiii., No. 3. July, 1930. Pp. 501–848.

Epidermoid carcinoma of the head and neck with special reference to metastasis, by R. A. Willis (Heidelberg, N.S.W.). A careful anatomical study of 20 cases of epithelioma of the mouth and adjacent parts. Remote visceral metastases occurred in ten cases, always from penetration of the large veins of the neck. Liver metastases are most frequent; they may penetrate the portal veins again and form the source of a secondary series of metastases in the liver.—The relative insusceptibility of young rabbits to streptococcus toxin, by H. J. Parish and C. C. Okell (London).—Gelatinous degeneration of the bone marrow, by P. Michael (Montreal). To be distinguished from œdema by the threads of precipitated fibrin about the periphery of the fat cells. Most commonly found with tuberculosis.—The ætiology of lymphadenoma, by C. C. Twort (Manchester). Six years' exploration of most of the possible avenues gave entirely negative results; some strange "bodies" are figured.—Phagocytosis by bronchial epithelium in the lungs of mice, by E. S. Duthie (Dublin). Some of the "dust cells" are derived from the epithelium of the bronchi.—Variations in the growth of the Jensen rat sarcoma and the influence of technique, by Helen Chambers and G. M. Scott (London). The rate of growth may vary enormously in different races of tame rats.—Experimental streptococcal infection and immunity, by A. W. Downie (Manchester). An important paper which should be studied in the original, leading to the conclusion that immunity to highly toxigenic moderately virulent strains is mainly antitoxic, while effective resistance to highly virulent strains is chiefly antibacterial.—The influence of cryptorchidism and of castration on body-weight, fat deposition, the sexual and endocrine organs of male rats, by V. Korenchevsky (London). Castration is followed by a decrease in body-weight, an increase of fat, atrophy of the penis, prostate, vesiculæ seminales and thyroid, and hypertrophy of the adrenals and pituitary. Bilateral cryptorchidism does not affect the pituitary or the body-weight; there is generally an increase in fat and a considerable atrophy of the penis, prostate, and vesiculæ seminales, and less constantly of the adrenals. Sexual hormones are produced by the seminiferous as well as Leydig's cells.—Bacteriophage reactions of Flexner dysentery strains, by F. M. Burnet and M. McKie (Melbourne).—Bacteriophage activity and the antigenic structure of bacteria, by F. M. Burnet (Melbourne). A very interesting discussion of the nature of bacteriophage action with the suggestion that it may be the heat-stable agglutinogens on to which phage particles are specifically adsorbed.—Observations on the variants of *B. subtilis* and their relations to the somatic and flagellar antigens, by N. C. Graham (London). Four variants are described with very marked differences in colonial appearance and bacterial form.—On the growth of endometrial transplants in the rabbit, by H. H. Gleave (Sheffield). The structure of endometrium transplanted into the liver of the same animal is the same as that in the uterus. Under the influence of corpus luteum hormone, œstrin, and oöphorectomy they show the same changes as the uterus.—Experimental cryptorchidism of pigs, by V. Korenchevsky (London). A coloured plate shows the complete disappearance of seminiferous tissue in the cryptorchid testes, the survival of the Sertoli cells, and an enormous overgrowth of the Leydig cells.—The action of certain dyes on the bactericidal activity of normal serum and on hæmolytic complement, by J. Gordon (Leeds). Congo red interferes with serum hæmolysis by combining with and inactivating the complement.—Vitamin D sclerosis of the rats aorta, by J. B. Duguid (Cardiff). The essential lesion is a muscle degeneration and calcification of the media similar to the lesions in adrenalin sclerosis in rabbits and Mönckeberg sclerosis in man; overgrowth of intima and fatty change are secondary.—Infectious ectromelia: a hitherto undescribed virus disease of mice, by J. Marchal (London). A general virus disease with lesions in the liver and spleen which often leads to gangrene and loss of a foot—hence the ill-chosen name. The cytoplasmic inclusion bodies are very large and abundant.—The titration of antipneumococcus serum, by H. J. Parish (London). Serum and culture are mixed, let stand for five minutes and then injected intraperitoneally into mice. There is no relation between the agglutination titre of a serum and its protective action.—The accuracy of titration of antipneumococcus serum, by J. W. Trevan (London). A mathematical examination of the preceding paper.—Atrophy of the adrenals associated with Addison's disease, by W. Susman (Manchester).—The incidence of atrophy and tuberculosis of the adrenal glands and their relation to Addison's disease, by F. F. Hellier (Leeds).—Adrenal atrophy in Addison's disease by W. G. Barnard (London) (see p. 148).—The irradiation of the blood in vitro, by A. Eidinow (London). Irradiation with a mercury-vapour lamp causes hæmolysis of red cells, destruction of leucocytes, methæmoglobin, and destruction of antibodies and complement. Intensely irradiated blood is toxic.—Transmission of maternal immunity, by J. H. Mason, T. Dalling, and W. S. Gordon (London).—Ligation of the hepatic artery, by G. R. Cameron and B. T. Mayes (London).—A direct method for counting the leucocytes, thrombocytes and erythrocytes of birds' blood, by A. F. B. Shaw (Newcastle).—Obituary of P. C. W. Laws.—Books received.—Proceedings of the Society, June 27th and 28th, 1930.—The soluble specific substances of pneumococcus type I: antibactericidal action skin reactions, by J. M. Alston, G. R. Galbraith and D. Stewart (Edinburgh).—The lowering of host resistance in experimental pneumonia, by J. F. Gaskell (Cambridge).—Septic thrombosis in puerperal septicæmia, by J. F. Gaskell (Cambridge). It is suggested that in some cases infection is kept up from an infected clot in the iliac veins after the uterus has returned to normal.—Asbestosis bodies in the lungs of guinea-pigs after three to five months exposure in an asbestos factory, by M. J. Stewart (Leeds).

NEW BRADFORD MENTAL INSTITUTION.—After seven years of discussion sanction has now been given to the erection by the Corporation of Bradford of a new institution for the reception of 240 mental defectives. The building, which will cost £105,000, is to be placed on the Corporation's Westwood estate at Clayton Heights.

THE LANCET.

LONDON: SATURDAY, JULY 19, 1930.

INSURANCE PRACTICE IN EUROPE: AN AMERICAN VIEW

In our issue of June 28th we took occasion to comment on a valuable report prepared by Dr. WILLARD C. RAPPLEYE as director of study of an influential American Commission on Medical Education. Though the report, further to consider which will be useful, consists chiefly of a study of medical education in certain European countries at the present time, it devotes attention also to the future career of the student after he has secured his hall-mark as a qualified medical practitioner. In this part of the report prominence is given to the conditions in which medical practice is carried on under the various European schemes of national insurance against sickness, for their working out has had a very important influence on medical practice in the countries in which they have been adopted. It is doubtful, indeed, whether the importance of that influence is adequately appreciated, even by the doctors who are engaged in insurance practice, and the sections of the American report which deal with the subject, and with unusual discrimination, may be studied profitably by all of us. For not only an interest in but sane comprehension of the principles of insurance practice is necessary for an appreciation of what the future may have in store for the profession of medicine.

The report shows that the modern development of national health insurance has brought about a fundamental change of view in regard to the objects it sets out to secure. Formerly it was thought that the chief aim of health insurance was to provide cash benefits for workers whom sickness had made incapable of work; the disabled wage-earner was given money to compensate him for the wages he had been compelled by sickness to lose. That is to say that insurance was then regarded as a form of compensation. It is now regarded as primarily a method of securing early restoration of working capacity. Compensation is recognised as an important, indeed an essential element in health insurance, but the main object now is to provide the treatment necessary to bring the patient back into a wage-earning condition. Restoration rather than compensation is the modern note. The results of this changed point of view are naturally most evident in the countries in which national health insurance has been longest in operation—namely, Germany and Austria—where the insured person is entitled not only, as in England, to the services of a doctor, but also to every kind of specialist and institutional treatment. Development along this line should call for our close consideration in view of the projected improvements in our own insurance service. In Germany, for example, the demands for specialist services have increased to such an extent that the insurance societies have felt compelled to adopt safeguards against abuse. Medicinal baths seem to be especially popular; the report gives an imposing list of 152,691 baths of 16 different types which in the year 1925 were provided for the insured persons of Leipzig as part of medical benefit. In the older insurance schemes medical provision has developed not only by the inclusion and steady extension of specialist services, but also by providing medical benefit to the dependents of insured persons, and here again the lesson may be informing in our own country. The report states that in Germany the insured persons, together with the dependents for whom medical benefit is available, form over 60 per cent. of the total population, while in some large towns the proportion of persons receiving benefits is thus brought to about 90 per cent. The significance of these developments will be obvious to our readers. Of the 47,000 medical practitioners in Germany it is estimated that not more than 5 per cent. are engaged solely in private practice; about 15 per cent. are in salaried positions, and about 80 per cent. are in the service of the insurance societies.

When insurance practice employs so many doctors, it is clear that the conditions peculiar to it are of vital professional importance, and some of the leading German insurance officials contend that the medical curriculum should include instruction specially devised to equip the student as a competent insurance practitioner. Pressure is being brought to bear on the medical schools to give more attention to the teaching of such subjects as the treatment of the diseases with which insurance practice is particularly concerned—e.g., rheumatism and the illnesses generally classed under this heading, the neuroses, common gynæcological conditions, the detection of malingering, and circumstances in which certificates of incapacity for work may properly be given. It is contended that doctors frequently certify patients to be incapable of work without due consideration of the various kinds of stresses involved in different occupations, and of the reactions of patients to work at varying stages of their illnesses. It is thought, for instance, that many patients certified as incapable of work on account of various forms of neuroses would be all the better in health if they went earlier back to work. Instruction in the medical schools on the precautions that should be observed in the issue of certificates of incapacity would, according to this view, enhance the efficiency of insurance practitioners and secure rational economies in the funds available for the provision of insurance benefits. There are enthusiasts who hold this view so strongly that they would wish to bring the medical schools somehow under some measure of insurance control. In all this our readers will see the reflection of views held or contested in this country. It is the British health insurance system, however, that receives most attention in the report, and the account given of the origin and operation of the

system is informative and accurate, except for some curious slips, such as the statement that the doctors' fees are distributed through the regional medical offices. The important part taken by the doctors in the administration of the scheme is pointed out, and the general conclusion is that national health insurance in this country has been advantageous both to the medical profession and the public. It is interesting to note that the results of this impartial survey, based as it is on careful inquiries made on the spot, are on the whole favourable to the system, whether regarded from the point of view of the doctors, the patients, or the public.

RETINAL DETACHMENT.

Dr. GONIN's treatment of detachment of the retina, which is referred to by Miss IDA MANN in another part of this issue, formed the subject of discussion, opened by Dr. GONIN himself, at a crowded session of the Oxford Ophthalmological Congress last week. Dr. GONIN's main thesis is that in every case of spontaneous detachment of the retina—i.e., cases apart from trauma, tumour, and albuminuric exudation from the choroid, it is possible to discover a hole in the retina if only we take enough trouble to look for it. The detection of this hole may be a matter of some difficulty, since it often lies far forward in the region of the ora serrata. The theory presupposes a partially liquefied vitreous, also the existence of vitreous tags adherent to the retina and thus capable of pulling on it, so that when a hole is made by traction there is free communication between the vitreous chamber and the inter-retinal space. Consequently, the only possible means of curing these detachments is to close the hole. This entails a most careful search, for the hole may be covered by a fold or may be too far forward to be easily visible. Typically it is of horse-shoe shape with the concave face directed outwards, but it may be round. If the lips of the hole can be sealed by means of the cautery the communication between vitreous chamber and inter-retinal space is permanently closed. Earlier operators who have employed the cautery have directed it towards the deepest part of the detachment, which is generally in the lower part; GONIN's new principle is to direct it always to the hole, which is often in the upper part. The success of his technique, then, depends first on the ophthalmoscopic detection and then on the accurate localisation of the hole. The fact that there have been undoubted cures following GONIN's procedure—the proportion of successes in recent cases is reported by him to be 60 per cent.—encourages the hope that a real advance in the treatment of this condition has been made. At the same time it would be wrong to encourage unjustified expectations of an infallible cure. In the first place, the method is only applicable to cases in which a hole can be discovered, and if the first attempt to close it is unsuccessful the operation may have to be repeated. In the second place, the holes may be multiple and a separate operation may be necessary for the closure of each. In the third place, even if the hole or holes have been successfully sealed, the condition which originally caused them—a diseased vitreous, or the stretching due to high myopia, or both—will still persist. Further, the operation itself is not free from risk; a hæmorrhage into the vitreous may occur which may make vision worse instead of better. At the Oxford Congress Mr. CHARLES GOULDEN reported that out of 11 cases in which he had performed the operation he had had nine successes but two had been failures from this cause. In this connexion the suggestion of Sir WILLIAM LISTER is valuable, that instead of allowing the cautery to penetrate as far as the detached retina itself, it would be better to stop it at the choroid, trusting to the adhesive inflammation set up opposite to the hole to close it.

In considering the prognosis of these cases it must not be forgotten that after having been detached for a period the retina loses its function. How long this period may be in any special case is unknown, but it is obvious that from the point of view of restoration of vision any operation is less hopeful the longer the detachment has been present. Also, it is a fact that, although the majority of cases of double detached retina at present inevitably end in blindness, there are cases in which a certain amount of useful vision is retained for years, even though the detachment persists. The possibility of making the vision not better but worse by operation must therefore never be overlooked.

The discussion at Oxford will long be remembered by those who were present and may mark the beginning of a new epoch so far as the treatment of detachments is concerned. So far only a few operators in this country have had practical experience of the method, but the results reported at Oxford were on the whole encouraging, and it is likely that others will familiarise themselves with a complex technique. Unfortunately, the operator cannot be guided by direct vision in directing the cautery. He has to find the hole with the ophthalmoscope, localise its position on the outside of the eye by minute and exact measurements, and then, after reflecting the conjunctiva, insert a Paquelin cautery at a place which his calculations have led him to believe is the right one. Ample warning was given at the Congress of the dangers of the procedure even in skilled hands, and it is unnecessary to emphasise here that the operation should only be attempted by those who have completely mastered the technique.

HOSPITALS AND MOTORING ACCIDENTS.

A YEAR ago we said in these columns, when drawing attention to the ominous prevalence of motoring accidents and the burden which this implied upon the hospitals and the medical profession, that, if the situation continued, legislation to relieve somehow and in some degree a scandalous state of affairs would be required. Last week an interesting debate ensued upon the point, and a certain degree of legislative remedy appears probable. Under the Road Traffic Bill the owner of a motor-car is required to take out an insurance

policy covering him against third party risks, while a subsection provides that, such a policy being existent and benefiting a third party, hospital expenses should be paid by the authorised insured in respect of the victims of motor casualties up to an amount not exceeding £25 for each person treated. In the course of the debate discussion was confined to consideration of the hard position of the voluntary hospitals, where beds are occupied by cases for which hospitality had never been contemplated, the claims for attention by individual practitioners not, apparently, being recognised in the Bill—at least in so many words.

The debate arose out of an amendment by Major HILLS to delete the subsection in question, and it must be admitted that he made a series of objections to the intended legislation which were logical. He pointed out that it would be a new departure in insurance law to call upon a motorist to pay, through the medium of a policy to an outside person, money which he was under no legal liability to pay at present; the provisions to bring this about would, he said, be exceedingly difficult to work. Further, he criticised the omission to extend the liability to vehicles owned by local authorities, and to drivers and their passengers. He was supported in his amendment by Mr. MORRISON, the Minister of Transport, who said that the matter was one upon which the Members of the House would be left free to express their opinion by their votes, a line of conduct which met with general approval. But the Minister then made a vigorous plea for State-run hospitals, finding in the position revealed by the debate one more argument for the taking over of the hospitals from their voluntary control. Mr. MORRISON saw in the inability of the voluntary institutions to meet the new and growing charge upon their accommodation and resources a vision that the State sooner or later would have to shoulder the burden, and, while he felt that those who voted to the detriment of the hospital finances might incur odium, he none the less found the challenged subsection a retrograde step. But although the proposer of the amendment and his supporters in the House, were able to criticise the terms of the clause effectively, no constructive proposals were forthcoming by which the immediate and growing evils could be met. The real effect of the passing of the amendment would have been that nothing could be done until the day arrived, if ever, when the establishment of State hospitals, over and above the present provision of this sort, was found by the country to be necessary. On this attitude two things call for obvious remark: first, there is no consensus of opinion that the voluntary principle has broken down, but on the contrary it has derived considerable strength from recent developments; and secondly, the admitted abuse of charities, often in pecuniary difficulty, must not remain indefinitely unrelieved.

Legislation is necessary, however illogical in its planning or difficult in its working, because the risk to life and limb is growing, and the number of persons who are trading upon the generosity of hospitals and individual practitioners seems to be growing also. The circumstances may often be unfavourable to the normal methods of charge and payment; the seriously injured person cannot arrange for the remuneration for his treatment, nor can this be expected from Samaritans who help him to hospital or surgery. We are happy to believe that the class of motorists that leaves its victims by the side of the road uncared for is quite a small one, and in this case if the offender makes good his escape it is clear that there is nothing to be done. But where elementary decency, aided sometimes by the fear of detection, leads the driver of the car which causes the accident to accompany the injured person to the place where medical succour can be given, he will yet hesitate to make himself responsible for the cost of treatment, and this not through meanness, but because any disbursement may present the appearance of admitting guilt, whereas it may be the intention strongly to contest that point. Much money to meet the heavy expenditure by hospitals upon motoring casualties may not be forthcoming through the insurance scheme, but, whatever it may turn out to be, it will be welcome.

BATHING IN THE SERPENTINE.

THE suggestion is made by *Civil Engineering* that a part of the Serpentine, containing some 3,000,000 gallons, should be enclosed by concrete and provided with a complete water purification plant. This brings up the large question whether people should ever bathe in large numbers in small open lakes. The Serpentine must, of course, be regarded as a large piece of water; it is nearly a mile long, and a rough estimate shows that its content is somewhere from 70 to 100 million gallons. Moreover, it is not altogether stagnant, for it was formed by damming the West Bourne, and this river still runs through the lake. In London we are not without experience of similar waters devoted to bathing; the Hampstead and Highgate ponds have been so used for years, and are not known to have spread disease. It is clear, however, that each bather must bring into the water a contribution of oxidisable organic matter and of bacteria. In water freely exposed to air, and containing a naturally balanced community of animal and vegetable life, the disturbance of equilibrium caused by a reasonable number of bathers would be small. In the Serpentine, assuming that there are a million bathers a year, the disturbance would be of the same order as the soiling of a large domestic bath by one bather, but this makes no allowance for the distribution of the million bathers over several months, and this provides the difference. On general æsthetic grounds the nearer the approach to natural surroundings the more pleasant things are for bathers and onlookers. It might, however, be wise of the Office of Works to have periodical analyses, chemical and bacteriological, of the water entering the Serpentine at the Kensington Gardens end, before it flows under the road bridge, and as it leaves the lake to flow over the fall at the eastern end. It is a great benefit to London that the finest sheet of water in the metropolis should be made available for a sport which has been too much neglected, but the two fatal accidents raise a doubt whether such a large, deep, and opaque mass of water should be used without restriction. Swimming baths are the only places where poor swimmers can bathe in perfect safety, and a good deal of protection and supervision may be required for young people.

ANNOTATIONS

THE OUT-PATIENT QUEUE.

In another part of this issue Dr. A. R. Friel offers suggestions for a time-saving reorganisation of ear clinics. A wider application of this sensible idea would rob hospital attendance of one of its most serious disadvantages in the eyes of the patient. It has recently been discovered that it is not essential to rouse in-patients at 4 in the morning to be washed; if it were also possible daily to save some thousands of persons three or four hours of wasted time, private practitioners would less frequently meet with evasion when hospitals are mentioned. For mothers with babies, attending children's departments, the long wait is particularly trying. Dr. A. G. Maitland-Jones at the London Hospital[1] has given expression to the difficulty of examining an overtired and irritable child. The nervous patient who has made the journey only after much encouragement and at the cost of considerable personal effort is rapidly demoralised by the delay; the busy mother is concerned for the uncooked midday meal, and the man from an office for the interruption of his business or that of his employer. Unfortunately, it is not easy to arrange an appointment system on so large a scale, especially where new cases are used for demonstration to students. Yet a certain order has been introduced into some clinics, notably at the out-patient department of the Birmingham General Hospital. It has been suggested that out-patient departments should be used for consultation only and not for teaching; if a social service were also established to relieve the physicians and surgeons of some of the clerical work, it would be possible for new patients to attend by appointment at half-hourly intervals on definite days. This would mean the loss of a very valuable form of instruction to the students, who probably see more variety in the out-patient department in an afternoon than in a week of ward rounds. The American system of a department open for the greater part of the day would reduce congestion but entail a much larger staff. The plan of working through the accumulated cases in batches, described by Dr. Friel, though admirable for an ear clinic, could scarcely be applied at a general hospital where all new cases must perforce be seen at their first visit. A possible alternative which suggests itself is that new patients only should attend at one session weekly. They should come by appointment for a consultation of length sufficient for the physician to make a provisional diagnosis and to estimate the interest of the case for teaching purposes. Old cases should attend on a different day, also by appointment, the length of the second interview having been estimated by the consultant at the first visit. It is not suggested that these estimates can be exact. The appointments could be made not to the minute but to the half hour; a period of waiting up to an hour or so is no more than the prosperous may have to suffer at the hands of dentists and specialists. The use of a little simple arithmetic of this kind on the part of the consultant or his house physician would avoid that exposure to students at the first interview which seems to be the dread of many patients. It should be possible, in any case, to devise some scheme to avoid the crowding of undiagnosed cases together for hours at a time. The canteens now opened for the patients at many hospitals, though a palliative, are a confession of failure in organisation.

[1] THE LANCET, 1929, ii., 79.

END-RESULTS OF EARLY SYPHILITIC MENINGITIS.

It has been known for some years that the cerebro-spinal fluid in about 50 per cent. of cases of secondary syphilis gives evidence of some degree of syphilitic meningitis. This may be slight or severe and in the latter case is often, but not constantly, associated with symptoms which indicate lesions of the spinal or cerebral nerve roots. This early involvement of the central nervous system is of great interest from two points of view. On the one hand its presence in the "latent period" after a year or more of active treatment is evidence that this treatment has been insufficient, and on the other hand it has been supposed, so far without any very definite proof, that cases of tabes and general paralysis are recruited from those who have had severe meningeal syphilis during the secondary period.

A paper by Paul Ravaut in the *Monde Médical* of June 1st goes some way towards confirming this supposition. His experience is a long one, dating back to 1903 when he first drew the attention of the medical world to the condition of the cerebro-spinal fluid in the early stages of syphilis, and the cases which he describes have been carefully watched over many years. He finds that cases in the secondary period may be grouped from this point of view into three main categories: (1) Those who never have any abnormality in the cerebro-spinal fluid. Among 91 such cases none developed later any evidence of neurosyphilis. In four cases the first puncture gave a normal fluid but a second puncture performed a few months later—i.e., still within the secondary period, gave a grossly abnormal fluid, and these patients developed neurosyphilis. (2) Those in whom the fluid showed only slight excess of cells and of protein with negative Wassermann and benzoin reactions. In practically all of these the fluid rapidly became normal and no further evidence of neurosyphilis appeared. In a few stronger fluid reactions were found at a later puncture, and some of these went on to neurosyphilis. (3) Cases in which the cerebro-spinal fluid, when examined within the first two years, was grossly abnormal, giving a high cell count and positive Wassermann and benzoin reactions. From this third group most of the cases of neurosyphilis were recruited, but in some the fluid cleared up and no later symptoms developed. When the reactions in the fluid disappeared slowly and incompletely the probability of the later development of neurosyphilis became considerable, and some patients developed tabes or general paralysis in spite of continued treatment. Malarial treatment, however, was not resorted to in any of these cases.

He found also that the changes in the cerebro-spinal fluid always preceded the clinical symptoms, and in some cases the fluid might be grossly abnormal for some time without any nervous sign appearing. This opinion was confirmed by Prof. Guillain, who examined several of Ravaut's patients at his request. But in the majority some slight clinical symptom or manifestation of nervous disease could be discovered. The practical lessons emerging from Ravaut's experience are, first, that the cerebro-spinal fluid should be examined during the secondary period, especially at the end of the second year; and secondly, that patients in whom grossly abnormal fluids are found should be carefully watched and treated until their spinal fluid becomes completely normal. Cases with

persistently abnormal fluids should be treated with especial thoroughness and, if necessary, subjected to malarial therapy, as it is probable that they are candidates for one of the chronic forms of neuro-syphilis.

ATMOSPHERIC POLLUTION.

THE fourteenth report of the investigation of atmospheric pollution covers the year ended March 31st, 1928. The early reports were issued as supplements to THE LANCET; then came a series from the Meteorological Office; this is the first report for which the Department of Scientific and Industrial Research is responsible.[1] The object of the investigation remains as before; it is to obtain exact information about the nature and extent of atmospheric pollution. But the form of the report is changing with the endeavour to make its main features easily and immediately intelligible to the layman. If this infinitely painstaking research is to produce benefits of practical value to the community, the results must be so expressed as to be readily assimilated by the public at large, and in particular by busy members of public authorities and their officials. The present report gives the results obtained from measurements of deposited impurity made with the standardised gauge, and suspended impurity as measured with the automatic filter and jet dust counter. Some data are also included on the measurement of daylight and ultra-violet radiation. Tar and sulphates, being practically entirely products of combustion, give the most trustworthy indication of smoke pollution, although carbonaceous matter, including soot, is very important. During the year the highest deposit of carbonaceous matter was found at Newcastle-on-Tyne, which station now holds the record for three consecutive years. The highest deposit of sulphates—viz., 140 tons per square mile—occurred at Burnley this year as last. The highest deposit of tar was at Salford (Peel Park and Regent-square), Newcastle-on-Tyne (City-road) coming next. The actual weight of tar deposited per square mile during the year at these stations was 36 tons at Salford and 20 tons at Newcastle. Side by side with current figures the report gives an average of the four or five previous years. On this basis London shows no improvement; at seven out of eight available London stations the sulphates and tar have increased when compared with the five years' average. Taking all stations together there is no general improvement. Tar is higher than the average in 11 and equal to or less than the average at 12 stations, while sulphates are higher in 22 out of the 23 stations. London and Glasgow illustrate the general tendency toward higher percentages of sulphates in the lower total deposits. It is somewhat remarkable that while a reduction of total deposit and of sulphates occurred in both cities from 1915–16 to 1921–22, improvement ceased about the latter date and there was a slight upward trend until 1927–28. The cause of this sequence is not obvious; an economic explanation has been suggested—namely, that the number of gas and electric heaters replacing coal fires reached a saturation point about 1921–22. It is curious that the changes should run so closely parallel in the two cities. The first appendix to the report by Dr. J. S. Owens shows the progress in using a scale of shades with the automatic recorder and in the matching of records. In the second, Dr. J. R. Ashworth surveys the pollution of the air in Rochdale. The fourth appendix describes generally the methods of measuring atmospheric pollution now in use. Finality is not assumed, and the Research Committee is engaged on the problem of measuring the sulphur compounds which cause such grave injury to buildings.

THE PREVENTION OF BLINDNESS.

THE welfare of the blind, as a world problem, has lately been the subject of a report by the League of Nations,[1] and it is now proposed to approach the prevention of blindness from the international standpoint. The initial impetus in this direction was given by the League of Red Cross Societies, whose secretariat, having undertaken to study the sphere of various charitable organisations throughout the world in relation to the preventive aspect of blindness, have come to the conclusion that the one in which this object was brought nearest to practical realisation is the United States National Society for the Prevention of Blindness. Last autumn, coincidently with the meeting of the International Ophthalmological Conference at The Hague, the International Association for the Prevention of Blindness was definitely constituted, with Prof. de Lapersonne, of Paris, as its president, Dr. Humbert, of the League of Red Cross Societies, as its secretary-general, and an executive committee of thirteen, of whom Dr. Bernard Cridland is the British representative, to meet annually in Paris. The main function of the association will be to coöperate actively with any existing society or centre for the prevention of blindness in the various countries, or endeavour to promote the creation of such a centre or society where it does not already exist.

The League of Red Cross Societies[2] has now published the report on which this movement has been based. It helps to reveal the difficulties of comparison in this matter between the various countries of the world; it also does much to lay bare the actual extent of the problem in different countries, and it displays the efforts which some countries have made to deal with it. The first difficulty is the definition of blindness, which can only be scientifically accurate at the expense of any practical utility. For practical purposes every country has its own more or less loosely defined standard of vision, below which the subject is considered to be blind. For comparable statistics to be possible, it is obviously necessary that some sort of standard definition should be agreed upon. A second difficulty is that the most complete tabulation of world-wide blindness available at the present time is already twenty years old (United States Census Report of 1919). The greatest single cause of visual impairment and blindness in the world is trachoma, a scourge which affects the majority of the population of several Eastern countries but from which Western Europe is comparatively exempt. In England, in recent years, it has become almost rare, and as the few cases which occur are almost always promptly dealt with, and the immigration of trachomatous aliens is checked, the actual blindness from this cause is now almost negligible in this country. Next to trachoma, syphilis, acquired and congenital, and gonorrhœa in the form of ophthalmia neonatorum, are responsible for a large amount of blindness in all countries, and the hygienic measures adopted to combat them are of the first importance. Other main causes of blindness are discussed under the headings congenital defects, glaucoma, disease, and accidents. It is remarkable that in Western countries cataract does

[1] See THE LANCET, 1929, ii., 831.
[2] Address: 2, avenue Velasquez, Paris.

not appear as a numerically important cause of blindness, a fact which must be due to the efficiency of modern treatment. Myopia is also a very small factor in the causation of blindness, though a very large one in the production of various degrees of impairment of vision.

An interesting annexe to the pamphlet describes a typical case of national action by the American National Society for the Prevention of Blindness. Its activities include various services under the following heads: eye infections of newborn babes; eye clinics for pre-school children (age 3 to 6); saving the eyesight of children of school age, especially in connexion with sight-saving classes for myopic and other children with defective sight; trachoma; and eye hazards in industry. The account of this national society is included in order that it may be of service as an example to other countries where similar action is called for. In our own country much has already been done to limit the spread of venereal disease and to ensure the prompt treatment of ophthalmia in the newborn, but there are three directions in which such an organisation as is proposed might render great service to the community. One is the spread of knowledge amongst mothers of young children below school age as to the dangers of untreated squint and developing myopia. A second is to urge the establishment throughout the schools in the whole country of special classes suitable for myopes and other children with defective sight, similar to those already existing in London. Lastly, the provision of safeguards against accidental injuries to the eyes in industry is a subject where there is room for voluntary effort, especially in the matter of the wearing of protective goggles by the workers in certain trades—a task which could only be undertaken with any chance of success by members of a society in touch with ophthalmic surgeons on the one hand and with both the management of works and the men's organisation on the other.

ADRENAL ATROPHY.

THREE papers in the current number of the *Journal of Pathology and Bacteriology* (vol. xxxiii., p. 749) call attention to the fact that "simple atrophy" of the adrenals is by no means an uncommon basis for fatal Addison's disease. Tuberculosis is so generally accepted as the regular cause that the occurrence of any other morbid anatomy is sometimes overlooked though atrophy has, of course, been included in the list of possibilities from the beginning. In Manchester Dr. W. Susman has 5 examples of atrophy in 6 fatal cases coming to autopsy; in Leeds Dr. F. F. Hellier found 3 atrophies in 9 cases; and at University College Hospital Dr. W. G. Barnard records 7 in 23. Adding these together we have 15 atrophies in 38 cases, or 39 per cent., the other 23 cases being all tuberculous. Other English statistics quoted by Dr. Susman give similar results; 3 in 8 at Birmingham, 7 in 29 at Guy's Hospital; whereas from Germany we have 1 in 15, from Norway 2 in 22, and from America 5 in 44, a total for non-English places of 8 in 81 or 10 per cent. It looks as if there might be some curious geographical difference in the incidence either of atrophy or of tuberculosis of the suprarenals. Two further points of interest emerge. "Simple atrophy" is apparently a misnomer, but whatever the nature of the lesion it has a strikingly uniform histological appearance and the pictures published by the different authors, here and in America, might well have come from the same specimen. Islands of large, swollen, more or less degenerate cortical cells lie in a mass of fibrous tissue with considerable infiltration with lymphocytes which are sometimes aggregated into small lymphatic nodes. The changes are strangely reminiscent of those found in the thyroid in myxœdema, and Dr. Susman actually describes collections of lymphocytes in the thyroid and pancreas in some of his cases. If the lesion is primarily inflammatory no one has found any evidence indicating the cause of the inflammation; alternatively it might be originally toxic and degenerative, and there is nothing which gives any decisive help in making the choice between these two alternatives. The other point of interest is that in several of the cases the cortex only is involved, leaving the medulla substantially intact—an important piece of evidence in favour of the view, so ably advocated by the late Prof. G. N. Stewart, that the cortex is the organ whose failure causes death in Addison's disease, and not the medulla.

A STUDY OF TUBERCULOSIS BY GENERATIONS.

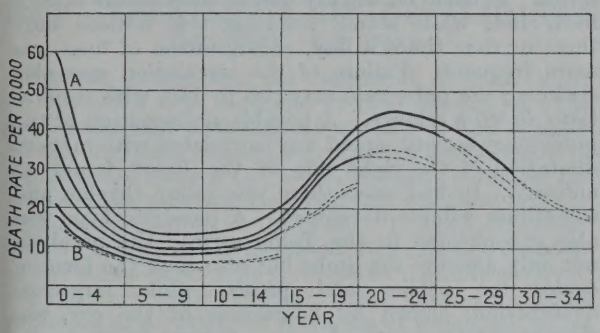
SOME two score years ago, a then obscure medical man in Norway published a statistical thesis whose gist was that the fatal pulmonary tuberculosis of adult life was merely the terminal stage of an infection in early childhood. This teaching was sheer heresy, and its author, Dr. K. F. Andvord, did not even enjoy the one privilege of heretics—persecution. He was simply ignored. And it was not till several years later that von Behring and his associates rediscovered this teaching which has now become acceptably orthodox. Meanwhile Dr. Andvord has completed a new study, which he has published in the *Norsk Magasin for Lægevidenskaben* for June, on the behaviour of tuberculosis in one and the same generation. He found that as far as towns and certain isolated areas were concerned, migration played too big a part to allow of a satisfactory study on the projected lines; but taking Norway as a whole, and noting the tuberculosis death-rate in five-year periods since 1896, he was able to follow the tuberculosis death-rate in the same generation, from childhood to middle age, and to compare the behaviour of one generation with another in this respect. The following table concerns some 300,000 persons in the

TUBERCULOSIS DEATH-RATE PER 10,000 PERSONS IN NORWAY IN VARIOUS FIVE-YEAR GROUPS SINCE 1896.

1896–1900	*34·2*	13·1	15·0	30·3	*45·0*	36·8	21·8
19.1–05	26·0	11·6	12·6	29·7	42·8	32·5	—
1906–10	20·3	9·5	10·9	27·4	34·0	—	—
1911–15	16·8	8·1	9·5	19·4	—	—	—
1916–20	13·9	6·4	6·3	—	—	—	—
1921–25	11·2	5·45	—	—	—	—	—
1926 & 27	10·2	—	—	—	—	—	—
Age-group	0–4	5–9	10–14	15–19	20–24	25–29	30–35

first five-year group, and some 200,000 persons in the same group when its members had attained the age of 20. In the first period, 1896-1900, the death-rate per 10,000 from tuberculosis was 34·2. It fell to 13·1 in the age-period 5–9, and rose to 45 in the age period 20–24. Taking each generation by itself in five-year groups, Dr. Andvord has prepared the chart here reproduced. The curve A represents the 1896-1900 generation, and the curve B the 1926-27 generation. From this chart Dr. Andvord argues

that once the death-rate from tuberculosis in the first five years of life in any generation is known, it is possible to calculate beforehand what it will be in the succeeding five-year periods of the same generation. He has already checked this claim,



confirming it by sending his forecasts of the tuberculosis death-rates in Norway in a sealed envelope to the Chief Tuberculosis Officer, Dr. Heitmann, with whose official returns Dr. Andvord's forecasts have hitherto shown a remarkable similarity.

BIRTH CONTROL.

THE practice of birth control has personal, marital, familial, racial and international implications, which have to be distinguished when judgment is passed on the subject as a whole. It is, perhaps, too soon to pronounce on its international implications, since not enough is known about the practice in different countries, and its relation to the ubiquitous fall of the birth-rate is still under dispute. It is possible, and desirable, however, to discriminate between the personal and racial aspects of contraception. In an address[1] by Dr. F. J. McCann, the President of the League of National Life, much stress is laid upon the medical harmfulness of contraceptive practices. The objects of the League of National Life are "to combat the theory and practice of Contraception; to oppose any form of State or Municipal assistance for the promotion of Contraception; and to uphold the honour and blessing of Parenthood." The League produces a monthly journal, *National Life*, the June number of which contains a supplement consisting of a symposium of quotations from speeches and writings of medical men condemning birth control.

In passing judgment upon the medical aspects of a subject so loaded with theological and moral implications as this, it is difficult to be detached. Dr. McCann claims to have formed his adverse criticisms impartially. He wrote in 1927 that his desire was "to seek the truth, not to manufacture a medical case against contraception."[2] This impression is not confirmed, however, by his use, in the course of his address, of such phrases as that the use of contraceptives is a degradation to woman, and that the practice of contraception is a deadly evil. The harmful effects of birth control were described fully by Dr. McCann in an earlier paper which was reviewed in THE LANCET of Nov. 19th, 1927, p. 1109.[3] In his more recent address nothing new is added. Dr. McCann selects for condemnation methods that are never advised at the birth control clinics. Thus corrosive sublimate (which is stated to be frequently used) and lysol are, so far as we know, never advised at birth control clinics. If, as Dr. McCann states, these substances cause mercurialism and vaginitis respectively, this must occur in women who use them without medical authorisation or advice. It would hardly seem logical to argue from this that the practice of contraception should not be medically supervised through municipal assistance. Dr. McCann's case in opposing such a measure would be immensely strengthened if he could quote instances of harm having been ascertained to follow from the use of methods of contraception that had been medically advised and medically supervised. Such cases, however, if they exist at all, are far from common, since the woman is examined and questioned about her health at each six-monthly visit which she is asked to make to the birth control clinic, and ill effects would be noted and corrected. A considerable body of evidence invalidating Dr. McCann's conclusion has been accumulated at these clinics. This evidence is entirely overlooked by those anti-birth control propagandists who make it their chief line of attack that birth control injures health.

The situation is otherwise, however, when the racial issues are considered. Though there is little or no evidence that contraception when medically controlled is physically harmful, there is abundant evidence that the existing methods, even when carefully taught, are found to be impracticable and unreliable by many people, particularly those of low grade stock. For the "social problem group" of the report of the Mental Deficiency Committee, existing methods are probably next to useless. All of them, with the exception of the intra-uterine ring, require forethought, self-control, or after care. They are, therefore, impracticable by persons who do not possess these qualities. A fairly thorough survey of the first 1000 cases that attended a London birth control clinic justified the statement that "The clinics have been powerless so far, to reach the obviously inadequate, mentally, socially, and economically," and "to limit the reproduction of those fertile individuals who constitute a serious problem—the feeble-minded, the insane, the chronic paupers, and the persistent leaners upon the State."[4] The author of this survey, Mr. Norman Himes, has recently published a statistical summary of certain of his findings relating to the types of contraceptive method recommended by nine British birth control clinics.[5] These conclusions are of very great interest to those concerned with the technical aspects of contraception, and they indicate that further coördination is needed in the medical services of these clinics. The most noteworthy of Mr. Himes's findings is this: Up till 1927, the most favoured method at the nine clinics on whose records the investigation is based, was the Dutch pessary, which was used in a total of 71·2 per cent. of cases. The desideratum with this pessary is that the largest size should be fitted which the woman can retain with comfort. Mr. Himes shows that there is much variation in the matter of the size most favoured by the medical officers of the different clinics. These pessaries are made in 14 sizes that range between a diameter of 55 mm. and 87·5 mm. At the Cambridge clinic, the most favoured size—i.e., that with which more women were fitted than with any other size, was one of 67 5 mm. At Glasgow, Wolverhampton, and Cannock, the most favoured size was 77·5 mm. It is far more likely that these wide variations in the most favoured size, amounting to as much as 10 mm., express different standards on the part of the medical officers than different pelvic conformations of the

women in the different localities. Indeed, it does not seem impossible that the high percentage of failure shown by Mrs. L. S. Florence to have occurred among the first 300 cases that attended the Cambridge clinic (see THE LANCET, April 16th, 1930, p. 919) may have been attributable to the fact that these women were fitted with pessaries of uniformly too small a size. It is to be noted, however, that though failures could be caused in this way, genital disease could not. There is no evidence in Mrs. Florence's book that the methods taught at the Cambridge clinic caused disease.

THE END-RESULT OF RAMISECTOMY.

THE authoritative pronouncement on p. 127 leaves no hope that the operation of cervical or lumbar ramisection, as performed by Mr. N. D. Royle, is of permanent value in the treatment of spastic weakness. It will be remembered that the operation was devised by the late Prof. J. I. Hunter and Mr. Royle on theoretical grounds for the alleviation of those cases of spastic paraplegia due to an excess of "plastic tone" (Sherrington), but not for those in which the "contractile tone" (Langelaan) alone is responsible for the condition. When Mr. Royle, who works in Sydney, visited London in the summer of 1927 he addressed a meeting of the Section of Orthopædics of the Royal Society of Medicine, showing cinematograph pictures and photos of patients successfully treated by this method. He also visited Queen Mary's Hospital, Carshalton, and selected from a number of children submitted to him six cases likely to benefit from ramisection. These children have been under the care of Mr. Gordon Pugh, medical superintendent of the hospital, who made himself responsible for the supervision of the post-operative care, massage, and re-educative exercises, these being planned on the lines advised by Mr. Royle. These cases have been examined periodically by Dr. C. P. Symonds and by a group of the surgeons who sign jointly the adverse report on their progress which we publish to-day. The names of these surgeons, who include representatives of six of the London teaching hospitals, are sufficient guarantee that impartial and careful consideration has been given to the investigation. Their conclusions will be received with regret.

INFANTILE BERI-BERI.

VERY little is known in Europe about the effect of vitamin-B deficiency during infancy; indeed the text-books seem to dismiss it as of no importance. Some years ago, however, G. W. Bray was able to show that such deficiency was the underlying cause of a huge infantile death-rate among the breast-fed population of a Pacific island, and he gave an excellent account [1] of the clinical features of beri-beri in infants. K. Ohta [2] now reports that the big majority of 430 cases which he has studied at the University Children's clinic in Tokio were in breast-fed infants, and that in more than half of them the symptoms began in the second and third month. In two-thirds of the cases the mothers had suffered from beri-beri either during pregnancy or after the birth of the child, but the severity of the disorder in baby and mother did not run parallel. Various types of infantile beri-beri are recognised. The commonest begins with symptoms very like those of any other gross nutritional disorder — e.g., pallor, loss of weight, inelasticity of the skin, and a fall in the intake of food. Vomiting is an early sign, associated with the passage of green stools, and it was present in 80 per cent. of the Tokio series. It came on usually one to three hours after a feed, and, while actual vomiting was noticed only three or four times a day, regurgitation of food was more frequent. Failure of the circulation was also striking; the pulse-rate may rise to 160, with respirations 40–60 a minute. A notable accentuation of the pulmonary second sound was correlated with marked dilatation of the right side of the heart found at autopsy. In bad cases there was gallop rhythm and sometimes œdema developed. A paralytic type was also encountered in the Tokio series; the paralysis not only affected the limbs but also took the form of oculomotor palsies and ptosis, while laryngeal dysfunction, shown by hoarseness of the cry, was present in 83 per cent. of cases. Sometimes there was retrobulbar neuritis leading to optic atrophy, and sometimes the disease produced meningeal symptoms. Ohta urges that prophylactic treatment of the mother should be the rule, but when a child has actually got beri-beri it should be weaned at once, though one or two breast feeds may, perhaps, be allowed after a few days. With T. Izumita [3] he has investigated the shape and peristaltic movements of the stomach in infantile beri-beri, but found nothing abnormal. It was shown, however, that milk from women with beri-beri remains much longer in the stomach than milk from healthy women, and also longer than cow's milk. This was also true for normal infants and points to a fault in the milk itself. Apparently the delay bears no clear relation to the child's intake of vitamin B.

[1] Trans. Royal Soc. Trop. Med. and Hyg., 1928, xxii., 9.
[2] Jahrbuch. f. Kinderh., 1930, cxxviii., 1.
[3] Ibid., p. 10.

John Farquhar Fulton, M.D. Harvard, M.A., D.Ph. Oxf., Fellow of Magdalen College since 1928, appointed Sterling Professor of Physiology at Yale University Medical School in July, 1929, with a year's leave of absence, is moving to New Haven in August of this year.

THE MANOR HOUSE ORTHOPÆDIC HOSPITAL.—Mr. A. V. Alexander, First Lord of the Admiralty, recently laid one of several foundation-stones of a new wing of this hospital at Golders Green. The wing is part of a scheme that will cost £350,000, and when completed the building will hold 300 patients. The hospital is maintained by the Industrial Orthopædic Society, which has a membership of 160,000 who subscribe a penny a week each. Some 50,000 of the members are employed on the north-east coast; another 25,000 are employees of the London General Omnibus Company.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—At a quarterly court of the directors on July 9th the sum of £2151 was voted in grants. At the present time there are 51 recipients on the books. The sum mentioned above was for the half year July 1st to Dec. 31st. Widows received £37 10s. if over 65 years of age, and £35 if under 65, orphans each received £25. Relief is granted only to the necessitous widows and orphans of deceased members of the society. Any widow of a member who is left with an income of £125 or under is eligible to such relief as the court of directors think fit. Membership is open to any registered medical practitioner who at the time of his election is residing within a 20 mile radius of Charing Cross. The society's address is 11, Chandos-street, Cavendish-square, W.1, and further particulars may be had from the secretary.

MODERN TECHNIQUE IN TREATMENT

A Series of Special Articles, contributed by invitation.

CCCII.—TREATMENT OF DETACHMENT OF THE RETINA.

BEFORE considering the treatment of detachment of the retina it is necessary to deal shortly with the ætiological and pathological aspects of the subject. In the first place it must be realised that the plane of separation at which the retina becomes detached lies between the rods and cones on the one hand and the pigment epithelium on the other. It is not, therefore, strictly speaking a detachment, but rather a cleavage of the retina in an embryonic plane (i.e., the cavity of the primary optic vesicle). This cleavage can be produced in a variety of ways, all of which fall either under the heading of pressure or of traction. That is to say, the retina may either be pushed off by the pressure of something on its choroidal aspect or pulled off by traction from its vitreous surface. It is important to realise these two types since the ætiology, and therefore the treatment and prognosis, is often very different in the two groups. (It is, of course, possible that trauma may act in either direction.)

Detachments Produced by Pressure.

Our first group (of detachments produced by pressure from the choroidal aspect) will be composed principally of cases of new growth or of inflammatory exudate from the choroid. These must be carefully diagnosed from the cases of so-called idiopathic or spontaneous detachment, which fall mostly into the second group, since the treatment and prognosis is much more clear-cut in the first group. It can be stated quite briefly.

1. *New growth.*—The growth is practically always a choroidal sarcoma, and early enucleation of the eye offers the only certain hope of cure. The prognosis for life is good if the eye is removed before extra-ocular extension has occurred. In cases where an only eye with good vision contains a sarcoma it is possible to try the effect of insertion of a radon seed directly into the growth. This has been successful in a certain number of cases.

2. *Inflammatory detachment.*—In these cases the retina is raised up by an albuminous or hæmorrhagic exudate from the choroid. There is no hole in the retina and if the inflammation can be got to subside the retina will in practically every case reattach itself. Rest, heat, either in the form of hot bathings or dry heat (electric pad or Japanese muff warmer), and atropine 1 per cent. to the eye are used in every case, while an attempt should be made to ascertain the underlying cause, which can then be treated by appropriate drugs (e.g., mercury, iodides, salicylates, or tuberculin). The prognosis, except in tuberculous cases, is good. Allied to these cases of inflammation are the cases of detachment of the retina which occur in the course of pregnancy toxæmia and more rarely in other forms of albuminuria. Here no local treatment is required, but treatment of the albuminuria will always lead to reposition of the retina. These cases are therefore the most hopeful of all detachments.

"Spontaneous" Detachments.

The second group of cases forms a marked contrast to the first in that the ætiology is not clear and the prognosis extremely bad. Some text-books even go so far as to give a hopeless prognosis as regards treatment, though all admit that spontaneous recovery has been known to occur in very rare cases. So-called spontaneous detachment of the retina may occur suddenly in a previously healthy eye. It is, however, more common in myopic eyes or in eyes which show evidence of antecedent slight choroiditis. There is often a history of a blow on the head or eye, which may have preceded the detachment by some weeks. The causative factors are not completely understood. Leber's theory appears to fit in with most of the facts. It states that detachment is preceded by degeneration and retraction of the vitreous, which may become unduly adherent to the retina at some point (usually in the situation of a minute patch of anterior choroiditis). Traction at this point by the shrinking vitreous will produce a tear in the retina, through which the fluid portion of the degenerate vitreous may reach the subretinal space and distend it. This theory fits in with the observed facts that small patches of choroiditis are common in eyes with detachment, that rents and holes in the retina can be found in practically every case of spontaneous detachment if carefully looked for, that they are often triangular in shape, are situated anteriorly, and are more common in the upper part of the retina, where most detachments start.

Treatment should be carried out in every case in which the detachment has existed for less than a year. The best results are obtained in recent detachments (up to four months), since the retina ultimately loses its function and even if reattached is of no use. Treatment can be divided into non-operative and operative. Most ophthalmic surgeons would prefer to commence with non-operative measures, since if these fail, operation can be undertaken later. It is, however, important not to waste too much time, especially since the success in a number of cases of the operative procedure described under (4) is now undeniable.

Non-operative Measures.

The patient must be kept in bed absolutely at rest with the head between sandbags in such a position that the detached area occupies the lowest position in the eye. This mode of treatment is therefore likely to show the best results when the detachment is in the upper part. The patient should be kept absolutely still for 6–8 weeks if the treatment is carried out to the full. In addition to absolute rest attempts are made to promote absorption of the subretinal fluid, by sweating (aided by injections of pilocarpine gr. 1/12 and hot air baths) by mercurial inunctions, by administration of iodides and purgatives, and by the application of a pressure bandage to the eye, though it is difficult to see how this last is supposed to act. Locally the eye is kept at rest with atropine, and dionin drops may also be used in increasing strengths beginning at 1 per cent., to increase the lymphatic drainage. The treatment is obviously very trying to the patient and should never be used on old people. In a certain number of cases improvement takes place but there is practically always a relapse later.

Operative Measures.

Operative treatment includes procedures designed: (1) to promote absorption of the subretinal fluid; (2) to let out the subretinal fluid; (3) to promote adhesions between the retina and choroid; and (4) to close the hole in the retina.

1. Subconjunctival injections are made, usually with hypertonic saline (4–8 per cent.) after cocainising the eye. They are made with a hypodermic needle as far back as possible over the site of the detachment. They are apt to be very painful and seldom appear to do much good. Mercury oxycyanide may be used instead of salt solution.

2. Most detachments start at the top, but the effect of gravity causes the fluid to collect at the bottom of the eye so that the originally detached portion usually becomes reapplied. The fluid in the lower part can be then let out by various means. The sclera can be punctured by means of a Graefe knife, or the fluid may be aspirated. Some operators make the puncture with a galvano-cautery and aspirate through the hole, others sear the surface of the sclera before puncturing, in order to promote a reaction in the choroid which should then adhere to the retina. Opinion is still divided as to whether the retina should be transfixed with the knife in making the puncture. Some observers advocate this, but most consider that the sclera and choroid alone should be cut. It is also possible to evacuate the fluid by making a trephine hole in the sclera over the site of maximum detachment. All these procedures may lead to improvement but relapse is common.

3. Adhesions between retina and choroid are produced by cauterisation, either by the Paquelin or the galvano-cautery. The former is preferable as it retains its heat better. The outside of the sclera alone may be cauterised or a puncture may be made. From time to time observers have attempted to produce a chemical inflammation by injection of irritants into the subretinal space or into the vitreous, but this method is dangerous and, usually leading to severe reaction, has been abandoned. Attempts have also been made to promote reposition of the retina by dividing any abnormal vitreous bands which may be present (Deutshmann's operation), but the technique of this is difficult and only applicable in certain cases.

4. If Leber's theory of causation is correct and the tear in the retina precedes the detachment, it would be rational to suppose that if the hole were closed the subretinal fluid might absorb, since we know that it does so in albuminuric detachments in which there is no hole. Gonin, of Lausanne, was led to this conclusion after working on the pathology of spontaneous detachment. He devised the operation which bears his name with this end in view, and the results are hopeful in suitable cases. Patients have remained cured since 1916, when the operation first came into use in Switzerland, and the method is steadily gaining ground, and is now universally recognised as of value. The procedure consists briefly in finding the hole ophthalmoscopically, in localising its position on the outside of the eye by ophthalmoscopic and external measurement, and, after reflection of the conjunctiva, perforating the sclera with a very fine Paquelin cautery as near the hole as possible. The subretinal fluid flows out and the area of retina containing the hole comes in contact with the area of choroidal reaction following the burn, and is firmly tacked down by the resulting scar. The results are good in cases where detachment with a single hole is present in an otherwise apparently healthy eye, some cases having remained cured for more than ten years. The results are naturally worse if the hole is very large or the eye degenerate, but if the first operation fails to seal the hole completely a second or even a third puncture can be made after an interval of about ten days. There is usually remarkably little reaction if the cautery is used as hot as possible. The method is deserving of wider use, since it has undoubtedly produced permanent cures of an extremely serious condition.

IDA MANN, D.Sc., M.B. Lond., F.R.C.S. Eng.,
Assistant Surgeon, Royal London Ophthalmic (Moorfields) Hospital; Ophthalmic Surgeon, Royal Free Hospital.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Capt. F. J. Gowans joins the staff at Haslar Hospital, in succession to Surg. Capt. A. McCloy, who resumes duty in the hospital ship *Maine*.

The following appointments have been made:—

Surg. Comdrs. R. N. W. W. Biddulph to *Victory XI.*, for H.M. Dockyard, Portland; G. E. D. Ellis to *Iron Duke;* and H. L. Douglas to *Victory*, for R.N. Barracks.

Surg. Lt.-Comdr. J. H. B. Crosbie to *Pembroke* for R.N. Barracks.

Surg. Lts. W. R. S. Panckridge to *Scarborough* and D. M. Beaton to *Danae*, on commg.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt.-Comdr. (D.) A G. D. Pridham to *Vivid*, for R.N. Barracks.

ROYAL ARMY MEDICAL CORPS.

Col. H. S. Roch, late R.A.M.C., is placed on half pay.

Lt.-Col. W. W. Browne, from R.A.M.C., to be Col.

Maj. H. J. Bensted, R.A.M.C., is appointed an Asst. Professor at the R.A. Med. Coll.

Maj. (temp. Lt.-Col.) A. C. Amy to be Lt.-Col., vice Lt.-Col. W. W. Browne.

Maj. R. W. D. Leslie to be temp. Lt.-Col.

ARMY DENTAL CORPS.

Capts. D. J. Isaac and H. O. Sumerling to be Majs.

ARMY PROMOTIONS.

The results of the examination for promotion of officers in the Regular Army, Indian Army, and Dominion Forces, held at stations abroad last March, are as follows:—

Royal Army Medical Corps.—Majs. S. J. A. H. Walshe, R. R. Thompson, W. McE. Snodgrass, and W. M. Cameron; Capt. K. Fletcher-Barrett; Lts. M. R. Burke, J. H. Anderson, D. B. O'Sullivan-Beare, P. J. L. Capon, H. W. Daukes, and A. T. H. Marsden.

Army Dental Corps.—Capts. F. F. Anslow and R. G. Law.

Indian Medical Service.—Lt. B. N. Hajra.

Royal Canadian Army Medical Corps.—H. M. Cameron.

In India the results are:—

Royal Army Medical Corps.—Majs. G. O. F. Alley, J. Bennet, H. B. F. Dixon, P. A. Opie, and D. C. Scott; Capts. C. W. Greenway and C. Russell; Lts. G. T. L. Archer, D. R. W. Burbury, De L. Carey, F. M. Collins, W. F. Cooper, C. L. Day, P. Dwyer, W. G. S. Foster, R. A. M. Humphrey, W. F. Lane, L. R. S. MacFarlane, S. R. M. Mackay, A. MacMillan, T. E. Moles, F. Mc. L. Richardson, W. R. C. Spicer, M. G. de L'I Sturm, J. E. Swyer, R. T. P. Tweedy, G. A. Walmsley, and T. F. M. Woods.

Army Dental Corps.—Capt. J. McCurdy.

Indian Medical Service.—Lts. (Prov. Capts.) M. L. Ahauja, C. A. Bozman, C. K. Lakshmanan, W. J. L. Neal, and T. C. Ramchandani; Lts. R. D. Alexander, K. F. Alford, E. A. R. Ardeshir, S. C. Bakhle, H. L. Batra, S. S. Bhatnagar, B. Chaudhuri, E. V. Claydon, C. F. J. Cropper, S. T. Davies, Lakshman Dass, J. P. J. Little, E. S. S. Lucas, S. M. K. Mallick, C. Mani, and A. V. O'Brien.

DEATHS IN THE SERVICES.

Col. George James Hamilton Bell, C.I.E., I.M.S., who died on July 19th in his seventieth year, was the son of the late Mr. Robert Bell, advocate, and was educated at Edinburgh Academy and at the University, where he graduated M.B., C.M., in 1882. Four years later he joined the Indian Medical Service and served with the Burmese Expedition from 1887 to 1889 (medal and clasp), and with the Lushai Expedition on the N.E. frontier which followed. Later he acted as civil surgeon in Bengal, and in 1892 returned to Burma as superintendent of gaols. In 1910 he became Inspector-General of Prisons. His work in this department was recognised by the award of the C.I.E. in 1914. Two years later he was made Inspector-General of Civil Hospitals in Bihar and Orissa, in which capacity he acted until he retired in 1920. Col. Bell married, in 1890, Violet Helen Mary, daughter of Mr. Lestock Reid Forbes, by whom he had a son and two daughters.

SPECIAL ARTICLES

CHRONIC OTORRHŒA IN SCHOOLS.

A PROBLEM OF ORGANISATION.

BY A. R. FRIEL, M.D. DUB., F.R.C.S. IREL.

SEVERAL clinics for otorrhœa have of late years been set up in connexion with the school medical service. One or more sessions of two and a half hours' duration are held at each weekly. It has been found that one session employing the methods described below is sufficient for the cases occurring in Tottenham—one of the outer districts of London in which the school population is 25,000.

The object of this paper is to show that it is necessary to consider not only the condition in each patient and the treatment suitable for this, but also to pay attention to organisation so as to ensure adequate treatment for considerable numbers, and thus abolish chronic otorrhœa from the elementary schools.

As this paper does not deal specially with the treatment that can be carried out in the clinic, this is only shortly described.

Treatment.

The *acute* cases are given glycerin with 1 per cent. of carbolic acid to use at home. The mother is asked to place the child flat on its side and pour a teaspoonful of the fluid into the ear and allow it to soak in for 10, 15, or 20 minutes by the clock once or twice daily, according to the severity of the case. When the discharge becomes distinctly less the glycerin is suspended, and boric powder is blown into the ear at the clinic once a week till the ear is dry. Very occasionally zinc ionisation is required. Many cases of acute suppurative otitis media show rhinitis. For this they receive diastolisation, the most valuable and generally applicable method of treatment for simple rhinitis known to me. Directions for its use in this as well as some other conditions can be found in the papers [1] [2] referred to below. The *chronic* cases are with rare exceptions given no home treatment, but are treated once a week or once a fortnight at the clinic. In many the disease is slight and recovers with one careful cleansing and the insufflation of boric powder. Cases of greater severity are given zinc ionisation. Boric powder is also useful here in absorbing any mucus poured out while the inflammation is subsiding. A certain number of mastoid cases in which the discharge is mucoid recover at the clinic. When the discharge from the antrum is purulent I believe that an operation is necessary. These need not attend the clinic again. When more than the one factor—sepsis—is responsible for keeping up suppuration in the ear, the additional factors, such as polypi, are treated first. When the septic area is difficult of access, though not totally inaccessible from the meatus, a special technique is used to make it accessible or to gain access to it. These are the cases which take so much trouble.

[2] Clarke, F. P. M.: Clin. Med. and Surg., September, 1929; January, 1930.

Organisation.

Organisation—that is, the arrangements for getting work done—aims at securing the maximum of results with the minimum of energy, time, and material. It seeks to eliminate waste. It is intimately concerned with details. For example, when a mother brings her child to the clinic her work at home is at a standstill. If we do not keep her waiting we are more likely to secure her help and the regular attendance of the child. A written appointment is therefore given to each patient, and they are seen in their order in the appointment book. This avoids congestion, hurry, and irritation, and also insufficiency of treatment.

When a clinic of this sort is started in a district, the first difficulty which is met is the accumulation of patients. This is dealt with by calling them up seriatim in such numbers as experience shows can be dealt with at a session, diagnosing in each case what is keeping up the suppuration, and deciding whether the causal factors can be treated in the clinic or whether a mastoid operation is needed. The accumulation is worked through and it is then possible to start treating every fresh case of otorrhœa as soon as it occurs, and so prevent the great majority from becoming chronic. After three years it was found

TABLE I.—TOTTENHAM EDUCATION COMMITTEE: REPORT ON CASES TREATED AT AURAL CLINIC, 1924–29.

Nature of disease.	Cases. (ears).	Cured.	Ceased to attend.*	Still under treatment.	Needing operation.	Cured cases.			
						Visits made till discharge ceased.		Cases which had—	
						Total.	Aver.	Ionisation.	Recurrences.†

(7) Mastoid disease	86	18	20	2	46	72	4	11	3
3. External otitis	73	62	11	—	—	179	3	7	3
4. Not diagnosed and other conditions	32	18	12	2	—	32	2	5	1
Totals	839	628	133	14	64	—	—	—	—

* Of the cases shown as "ceased to attend" a proportion had left school at 14 years of age, or had removed from the district.
† The numbers were the ears which are known to have had one or more fresh attacks of otorrhœa.

that (omitting those cases due to mastoid disease), the number of chronic cases which could be detected in the schools at Tottenham was almost nil. Experience at the Hornsey and Walthamstow school aural clinics confirms the experience at Tottenham.

The organisation consists in bringing to each session only such numbers as can be efficiently treated, arranging that these are spaced out over the time so that haste is not necessary, and also that the time of the patient and his relations is not wasted. Recovery without damage to the hearing depends upon the possibility of getting the patients at the period when disease is most amenable to treatment. The elimination of the chronic cases renders this possible.

Table I. is an analysis of the nature of the disease, a statement of the frequency of the conditions met, and a summary of results. In the cured cases the average number of visits till the discharge ceased and the number of ears which had ionisation and also the number of recurrences are stated. In the column marked "ceased to attend" in Table I., some of the easy cases ceased to attend because the parent considered the child well and attendance unnecessary. On the other hand, in difficult cases—e.g., attic disease—they stopped coming because they saw no improvement. I have much sympathy with the latter. Before sending a child for an operation there should be a strong probability that he will leave the hospital with a dry ear and the hearing not made worse. Unfortunately in many districts this is not assured.

"Recurrences," or rather reinfections, in young children, are usually due to attacks of rhinitis, and in older children to water entering the ear in bathing, swimming, or washing the head. Many of these cases return to the clinic of their own accord and usually recover rapidly without ionisation.

TABLES II. AND III.

	1926.	1929.
Average number of cases seen per session ..	18·9	25
Average total time per case spent at clinic .	20·9 m.	16·9 m.
Average time per case kept waiting before seeing aurist	7·5 m.	5 m.

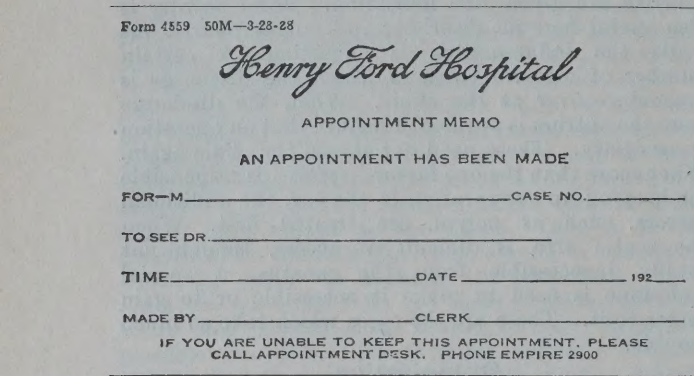
m. = minutes.

N.B.—In 1926, 15 per cent. of the cases seen were in the acute stage; in 1929, 45 per cent. of the cases were in the acute stage, and there were very few difficult "chronic" cases.

Tables II. and III. are compiled by Mr. Cohen, the organising clerk, for separate periods of six months.

HENRY FORD HOSPITAL.

In Detroit I had an opportunity of visiting Henry Ford Hospital, where a system of appointments is adopted (see figures), and I did not see any waiting-hall. It is evident that avoidance of waste of time, energy, and material makes for progress in clinical research, and that if we do not pay attention to this we shall remain in the slough of an accumulation of people who are sick. In a laboratory, experiments are arranged to solve single problems, but in a clinic, solutions are sought in a mixture of problems in living patients. This mixture is there analysed and the reaction of the tissues to the treatment studied.



Form 4559 50M—3-28-28

AN APPOINTMENT HAS BEEN MADE

FOR—M_____ CASE NO._____

TO SEE DR._____

TIME_____ DATE_____ 192____

MADE BY_____ CLERK_____

IF YOU ARE UNABLE TO KEEP THIS APPOINTMENT, PLEASE CALL APPOINTMENT DESK. PHONE EMPIRE 2900

IMPORTANT INFORMATION FOR PATIENTS WITHOUT APPOINTMENT

PATIENTS WHO DO NOT MAKE ADVANCE APPOINTMENT TO SEE A DOCTOR WILL BE REQUIRED TO WAIT UNTIL THEIR HISTORY IS OBTAINED FOR THE DOCTOR AND UNTIL OTHER PATIENTS WHO HAVE MADE ADVANCE APPOINTMENT ARE PROPERLY TAKEN CARE OF. ADVANCE APPOINTMENT CAN BE SECURED AT THE APPOINTMENT DESK OR BY CALLING

EMPIRE 2900

BETWEEN 8:00 A.M.—6:00 P.M. DAILY EXCEPT SUNDAYS AND HOLIDAYS

The Best Policy.

To sum up, the basic factor in the recovery of a patient is the treatment he receives; if we have a good treatment for any particular disease, we have a chance of abolishing the disease. But organisation is necessary to make this economically possible. There is now a great deal of unemployment and poverty. The medical profession may contribute something to the solution of the country's economic problems by seeing to it that there is no waste of energy, time, or material in the organisation of treatment.

I am convinced, basing my conviction on the sure ground of experience, that by the adoption of a correct policy, by paying special attention to organisation, and by adopting treatments which have proved to be rapidly successful, the abolition of chronic otorrhœa from the elementary schools is a practicable proposition.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

JAMAICA GINGER MULTIPLE NEURITIS.

A FEW months ago the newspapers were filled with stories of a strange epidemic of paralysis that had smitten the population of Oklahoma. Gradually it was revealed that a large proportion of the victims, ultimately as many as 95 per cent., could be brought to confess to the drinking of Jamaica ginger or "Jake," as it is sometimes affectionately called. The habit of drinking Jamaica ginger is not new in Oklahoma, large quantities have been consumed without alcoholic neuritis resulting, but in these days alcohol may be other things beside ethyl hydroxide. Some of the Jake victims apparently had taken very small quantities, and it is significant that the outbreak should have been so strictly limited in time. The medical aspects of this outbreak were discussed at the recent meeting of the Oklahoma State Medical Society. Neurological examination of the cases had revealed: (1) Steppage gait; (2) positive Romberg test; (3) absent Achilles reflex; (4) bilateral foot drop; (5) diminished vibratory sensation in both legs; (6) absent vibratory

sense perception in toes; (7) marked tenderness of the affected motor nerves; (8) pain, tactile and temperature perception unaltered. All attempts to isolate the toxic factor thus far have failed. Lead has been suspected, but no gastro-intestinal symptoms or other concomitant signs of lead poisoning have been present. Faradic response of the muscles was lost early, galvanic response is altered both quantitatively and qualitatively. An autopsy on one of the patients who died (not from the neuritis) showed on section of the medulla-cord slight œdema and thickening of the meninges. A perineural exudate, consisting mostly of lymphocytes, was found in a section of the cauda equina. Section of the anterior tibial nerve showed great thickening of the perineurium. Subsequent work showed degeneration of the anterior horn cells of the spinal cord. Invalidism seems to last at least for several months. The final outcome is still uncertain.

PREVENTION OF TRAFFIC ACCIDENTS.

For the prevention of traffic accidents the Federal Bureau of Home Economics has suggested that children be dressed in bright colours. The American Automobile Association, noting this suggestion, has presented 2000 yellow rubber rain capes and hats to schoolboys helping to control traffic in Washington, D.C. According to the *United States Daily*, the loss of life from traffic accidents for last year amounted to not less than 31,000, which is an increase of 10 per cent. over the deaths from this cause in 1928, and an increase of 147 per cent. over the figure for 1920.

NATIONAL INSTITUTE OF HEALTH.

Both houses of Congress have passed an Act, which the President has now signed, establishing a National Institute of Health. An initial appropriation of $750,000 is made for the construction and equipment of buildings. The Secretary of the Treasury is authorised to accept donations for use in ascertaining the cause, prevention, and cure of diseases affecting human beings. Research fellowships will be available for work within the institute, and subsidies will be granted for research both in this country and abroad. According to Senator Rausdell, author of the Bill, the encouragement and subsidising of research is the most important function of the institute.

An important pronouncement in connexion with the use of the radio to promote fraudulent "remedies" is made by Mr. W. E. Humphrey, a member of the Federal Radio Commission. "Publishers, advertising agencies and the radio stations hereafter must be prepared to defend any advertisements they handle," he says. The Commission will make the radio station parties in all actions brought against the advertisers. He appeals to physicians to aid the Commission, which has few funds at its disposal, by giving expert testimony whenever this may be necessary to convict an advertiser of fraud.

The control of medical work in the Federal prisons has been turned over to the U.S. Public Health Service, at the request of the Attorney-General. This is part of a general tendency to coördinate the different medical services of the Federal Government, and it should result in much needed improvement of the medical work in Federal prisons.

KING GEORGE HOSPITAL.—The six foundation-stones of the new buildings were laid recently by the Lord Mayor of London, the Lord-Lieutenant of Essex, Sir Cecil Levita, chairman of the London County Council, 1928-29, the Mayor of Ilford, and the Chairmen of the Urban District Councils of Barking Town and Dagenham.

BRITISH EMPIRE CANCER CAMPAIGN.

SEVENTH ANNUAL REPORT.

IN presenting their seventh annual report the Grand Council of the British Empire Cancer Campaign indicate the development of their organisation from small beginnings. There is now a headquarters staff, an intelligence department, and a system of coördination by which duplication and waste of effort is reduced to the smallest possible proportions.

The investigations subsidised cover a wide range and include experiments on the artificial production of cancer, tissue culture, studies of the biochemistry and metabolism of malignant tumours, and of methods of treatment. Chemotherapy by the heavy metals is being tried out under various conditions at some centres, and X ray therapy at others, but mostly there is concentration on perfecting their technique of treatment with radium. "The progress accomplished in the past year is indicated in the extension of radium therapy to new types of cases, in the modification of technique, in application of fresh methods of radiation." This statement, quoted from Mr. Stanford Cade's report on work at the Westminster Hospital, would apply equally well to other centres where radium is being used, and is true for clinics which have only recently started this form of treatment, as well as for those whose experience of it now extends over several years.

The bulk of the report, as in previous years, is taken up by records of work carried out at various centres. These are compiled by the institutions and individuals in receipt of grants, and it is made clear that the various committees of the campaign assume no scientific responsibility for the statements of fact or opinions contained in them. Unfortunately, however, in the foreword, signed by Lord Reading, which precedes these accounts, no indication is given where in the text fuller details can be obtained of the results quoted. For example, the following paragraphs in the foreword (p. 13) suggest that the difficulty of obtaining a supply of animals afflicted by spontaneous tumours has been surmounted.

The passage states:

"A strain of mice, some 94 per cent. of the females of which develop mammary cancers, has been obtained from America, through the kindness of Dr. Burton Simpson, of Buffalo, who obtained it by inbreeding from tumour-bearing parents for some 30 to 40 generations. In November, 1928, six females and three males of this strain reached England. They have been bred with great care and their progeny now numbers about 1000. Of the original six females one died of pneumonia; the other five have now all developed spontaneous cancers. These cancers grow rather slowly, but they go on growing and always cause death in about three to four months, producing meanwhile secondary growths exactly in the manner of cancerous tumours in man.

"It is too early as yet to say whether or not 'auto-vaccination' will prove effective in the case of these spontaneous tumours; indeed, a year or longer may be required in order to determine the point. There is, however, some hope of success. If the results obtained seem to justify the step, treatment of human cases will be undertaken at the earliest moment."

These statements seem to imply a general agreement among the workers, but are, in fact, abridged from the report by Dr. T. Lumsden of his personal work, experience, and hopes. The disappointing experience of this same strain of tumour-bearing mice recorded in the report from the Cancer Hospital, London (p. 26), is not chronicled.

"We were fortunate in obtaining from America, by the kindness of Dr. Simpson, of Buffalo, a strain of mice in which the females develope spontaneously mammary

carcinoma in about 90 per cent. of the cases. We have closely inbred this strain, but in a period of over 18 months not a single case of carcinoma has developed. It is true that the inbreeding has decreased the fertility, but it has not accentuated the supposed inherent disposition to cancer. . . . An attempt was made by repeated trauma of the mammary gland in some of the females to call forth the supposed inherited predisposition, but no response was elicited." In commenting on these negative results the workers at the Cancer Hospital state only that it would be unwise so soon to conclude that the tumours found in the strain in Buffalo are not attributable to hereditary disposition but to some exogenic factor.

It would thus be unwise to assume, as the format suggests, that the foreword represents a sort of bird's-eye view of the general conclusions reached, the compilation of which would admittedly be a hard, if not an impossible, task. Any misapprehension could be avoided in future reports either by the insertion of page numbers, indicating where in the report any work summarised is described, or by the addition of a good index.

We select for notice the searching work being carried out in various centres on

Carcinogenic Agents.

At the Cancer Hospital Research Institute the theory that any sort of chronic irritation of the tissues might predispose to the development of cancer, and that the main determining factor is the personal susceptibility, is not accepted.

The experience of Prof. A. Leitch and his colleagues has been that of substances closely allied chemically and physically some may induce neoplasia and others not, and they can discover no reason for this. It is only by trial of substances in the animal body that cancer-producing agents can be distinguished. In certain industries, such as briquette making and mineral oil refining, it is found that the noxious substances, pitch and crude oil respectively, are apt to induce epitheliomata in the workmen, whilst on the other hand chrome workers, for example, who are exposed to much more irritating substances that cause ulcerations, do not develop epithelioma in these exposed parts. Recently a deliberate test of potassium bichromate was made in a large series of mice, and though superficial and chronic ulcerations were produced in almost every case no tumour formation was seen.

It was discovered that several of the distillation products that produced cancer experimentally gave a very characteristic fluorescence spectrum, and that inactive substances did not exhibit this phenomenon. When a beam of ultraviolet light is thrown on a suitable solution of these active substances the photographic plate shows characteristic bands. This method has proved useful in giving a preliminary indication of what afterwards proved in test to be cancer-producing substances.

Attempts to induce cancer in mice by the application of the tar produced by tobacco smoking have been made at the Cancer Hospital, London, and also at Birmingham, without success.

CHEMICAL NATURE OF CARCINOGENIC SUBSTANCES.

Dr. F. D. M. Hocking (Westminster Hospital) notes that these carcinogenic substances are widely diverse as regards their chemical nature, but possess the one property in common of being fat soluble. He compares the list of substances known to give rise to cancer with one of drugs which act particularly upon the liver and result in hepatic degeneration. Such a list would include alcohol, chloroform, chloral, picric acid, T.N.T., arsenic, phosphorus, antimony, morphine, &c., all of which also have the common property of being fat soluble.

Dr. Hocking has tried to find out whether or not a precancerous toxæmia with some fat-soluble toxin which would attack the liver could be established. He states that in nearly every case of cancer, even when seen very early in the disease, the hepatic detoxicating functions are not only deficient, but are entirely absent, and makes the suggestion that cancer is caused by a fat-soluble toxin being present in the body for a very considerable period, perhaps for years ; for some time this toxin may be destroyed by the liver, but later hepatic degeneration (generally fatty degeneration) will ensue, and a state will be reached at which hepatic detoxicating action has been lost and free toxin is present in the body ready to attack some other tissue—i.e., at the precancerous state. It is further suggested that cancer is a degeneration, brought about in a manner exactly similar to that of any of the other better known forms of degeneration, by the action of a specific toxin, and that cancer cells, instead of being particularly virile, are, in fact, already on their way to death and can be killed outright by increasing the degree of toxæmia.

Dr. Hocking gives arguments to support this theory, and uses it to explain the success of treatment by radium.

It is well known, he says, that phospholipin, cholesterol emulsions or combinations enter largely into the composition of cellular membranes, and it is probable that they also form partitions within the cells themselves, thus physically shutting off one portion from another. Now, the interface between two physically immiscible bodies (such as fats and water in this instance) is always the seat of an electrical charge, so that such a static charge must reside on the surfaces of the phospholipin-cholesterol particles within the cell. If this charge is altered or neutralised cellular equilibrium is upset, particularly with regard to fat metabolism, and such a change is associated with malignant degeneration. As one of the characteristic properties of radium is to neutralise such static charges, it follows that irradiation of a normal tissue with radium will result in malignant degeneration if the dose is mild, and in death of the cells if it is severe. Irradiation of already degenerated cells—i.e., cancer cells—will therefore result in their complete destruction without influencing the normal surrounding tissues, always provided that these do not receive enough irradiation to cause their malignant degeneration.

According to this theory it is to the determination of the optimum intensity and extensity of radium irradiation that attention should be directed in the near future.

PHYSICAL PROPERTIES.

Mr. J. J. M. Shaw, working at the Department of Surgery in the University of Edinburgh, has carried out a series of observations on a large number of mice in order to determine the importance of the physical properties of the carcinogenic compounds in external applications.

A group of irritants, salts, acids, and alkalis, which are water-soluble and capable of dilution and removal by the tissue fluids, was contrasted with a group of viscous substances, tars, oils, &c., which are insoluble in the tissue fluids but which are capable of permeating the cellular strata and of holding the toxic moiety in prolonged contact with the cells in which the surface tension is also affected.

Papillomatosis and epitheliomata have been produced only by the latter group possessing the qualities of viscosity, insolubility in tissue fluids, and toxicity, and the indications have been that the specificity of carcinogenesis may lie in this physico-chemical complex and not in the nature of the toxic moiety which may be variable.

Whereas at the Cancer Hospital, London, attempts to induce cancer by applications of solid carbon dioxide merely produced, in 13 oz. of mice, papillomata which subsequently disappeared, Dr. I. Berenblum, working at Leeds, includes carbon dioxide among the "agents capable of inducing cancer." His experiments suggest that when two agents capable of inducing cancer are applied concurrently to the same area of skin the result may not be an augmentation of carcinogenesis but an inhibition. When each agent is applied alone for a certain period a summation of effect may be produced. The work in progress at Leeds on the anticarcinogenic action of dichloroethyl sulphide (mustard gas) has been

confirmed by the repetition of previous experiments and by further investigations.

Certain experiments devised to seek an explanation of this reputed inability of blast-furnace tar to produce tumours yielded conclusive evidence that samples of this tar are quite capable of giving rise to cancer under suitable conditions, though it is not so active as the horizontal retort gas tar.

INHIBITORS AND ACCELERATORS OF CARCINOGENESIS.

At Sheffield Prof. E. Mellanby and Dr. A. F. Watson have studied the effects of diet and other factors on the initiation and growth of cancerous tumours. Groups of mice have been maintained on varying types of diet and under different experimental conditions in each case for about 12 months, and the effect on the development of tar tumours has been studied. Care had to be taken to ensure that any inhibiting effect of a particular diet on the growth of the tumours was not producing its inhibition by adversely influencing the general health of the animals. The main results are not yet ready for publication.

One fact which is thought to have emerged from these experiments is that the development of tar tumours in mice depends on the ease of access of the tar to the reacting skin cells. It would seem probable that under ordinary conditions the tar makes use of its solubility in the skin fats to gain access to the reacting cells. If this fat is experimentally increased, for instance, by applying the same type of fatty substance obtained from other mice to the skin before applying the tar, then the cancerous reaction is strikingly increased. A similar, but somewhat less marked, effect is produced if olive oil is applied to the skin instead of the animal fatty extracts before the treatment with tar. Another method of accelerating the cancerous reaction in tarred mice is by maintaining the animals on a diet containing a high proportion, 20–25 per cent., of butter. Under these conditions the skin and hair of the mice assume a characteristic greasy appearance, and, presumably by facilitating the periodical absorption of the tar, the numbers of tumours produced are definitely increased. It might be anticipated that if the superficial skin fat is removed, either completely or partially, then the opposite effect—the inhibition of the cancerous reaction—would be found. That under certain conditions this is the case has been shown by treating the skin of the animals with petroleum ether—a typical fat solvent—before the applications of tar.

An interesting extension of these observations is that the increase or removal of the superficial skin fat not only increases or reduces respectively the skin tumours in tarred mice, but that a similar effect is produced on the tumours found in the lungs. Some of these are secondary to the skin tumours and some are of an adenomatous nature and usually regarded as primary lung tumours. In both cases, however, squamous secondary growths and epitheliomata, increase and reduction of the primary skin tumours, resulting from the treatment described above, result in a corresponding increase or decrease in the numbers and frequently the size of the lung tumours.

Dr. Harold Burrows has investigated further the possibility of introducing colouring and other matters into the cells of living tumours. He finds that permeation of the walls of the blood-vessels by colloid and particulate matters appears to be an early accompaniment of every method which produces cancer artificially (tar, X rays, ultra-violet light, irritation by cysticercus). It is, of course, a constant feature of local irritation whether this leads to cancer or not. But there are other conditions than inflammation in which such permeation occurs, and it may play an important part in those changes which lead to cancer. Dr. Burrows gives reasons for suggesting that the main mechanism of malignant metastasis is identical with the process of disposal of other fine particulate matter which gains an entrance to the blood or the lymphatic stream.

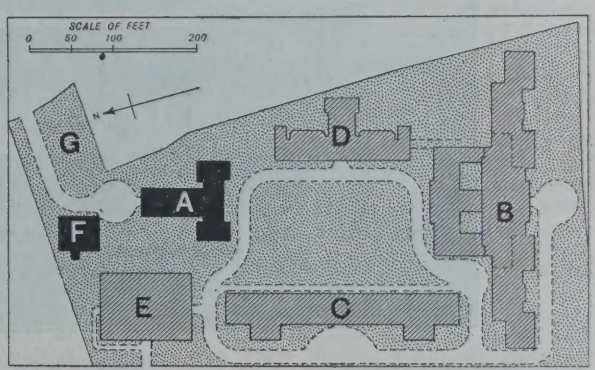
QUEEN CHARLOTTE'S HOSPITAL.

OPENING OF THE NEW ISOLATION BLOCK.

On July 10th Princess Mary, Countess of Harewood, opened the isolation block which is the first section to be erected of the new hospital in the Goldhawk-road, Hammersmith, to which the work of Queen Charlotte's Maternity Hospital will eventually be transferred. When completed the new Queen Charlotte's will be the largest maternity hospital in the Empire. It will eventually comprise the main hospital buildings, four storeys high, consisting of two 100-bed units and 48 prenatal beds (an annexe at the rear will contain the staff dining-rooms), the paying patients' block of five storeys with 80–100 beds, the administration block, students' college, and nurses' home, also of five storeys, the out-patients' block, antenatal and infant welfare department, the isolation block, containing beds for 30 patients and nurseries for 30 infants (now open), the research laboratories (now building), and the boiler house.

The whole of these buildings, which will accommodate 358–378 in-patients, will be grouped round a central lawn, according to the plan shown in Fig. 1, and are so planned that all wards look out on green trees and grass.

FIG. 1.



A = isolation block. B = main block. C = administration block, students' college and nurses' home. D = paying patients' block. E = out-patients' block. F = boiler house. G = site for laboratory. A and F only are now complete.

The Isolation Block.

The isolation block will be used for septic cases, and will be ready to receive patients in a few weeks. Sir Almroth Wright, who spoke at the opening ceremony, said that the building would be devoted to the study of puerperal sepsis. The deaths of mothers from this cause were not decreasing in number. The resources hitherto available had not been successful in coping with puerperal sepsis, and new ones would have to be looked for if what Sir Almroth described as one of the greatest problems of the world to-day was to be solved.

The isolation block has been laid out by the architects, Messrs. Edwin T. and E. Stanley Hall, in the form of a "T," of which the top faces due south, the leg running north and south. The top consists of three storeys, each floor having one five-bed ward, five single-bed wards (of which two are for paying patients), and a nursery for ten infants. The leg, which is only two storeys high, has a central corridor,

from which various offices open to right and left, whilst the first floor corridor is expanded at the north end to the octagonal lobby of the operating theatre.

On the ground floor are rooms for the honorary staff and for the resident medical officers, and also the dispensary, waiting-room for patients' friends, the receiving-room, nurses' duty room, and ward kitchen. This floor is connected by a covered way with the temporary nurses' home, situated in an adapted villa on a site which will later be occupied by the out-patients' and antenatal department. On each floor the five-bed wards have French windows opening on to broad teak balconies on the south side, on to which the patients can be wheeled in their beds. The single-bed wards face south, and all beds have the necessary connexions for a bed lamp, a bell, and the wireless. An observation window in the door of the single-bed wards, closed by a bronze disc, enables the nurse on duty to keep an eye on her patient. The nurseries are at the east end of the building.

Each of the three floors contains a duty room for the nurses and a ward kitchen, the latter giving on to a space provided for an electric service lift to link up the ward kitchens on each floor. All the corridors are lined with pale buff tiles to a height of 5 feet and the walls and ceilings throughout are treated in buff. All corners are rounded off, and all doors are in polished teak. The door and other fittings throughout are in roanoid, which only requires wiping, and is acid- and fire-proof. Taps, bed-pan racks, and other fittings are chromium-plated. All the paintwork is cellulose, brushed on to provide a good finish.

Sterilisers and Laundry.—The sterilising equipment is ample. On each floor is a room for sterilising the mackintosh bed sheets, a provision which is a new departure in hospital planning. The sink rooms for dealing with the bed pans have a sink fitted with a jet and douche over which the pan can be inverted. A large steam steriliser completes the work, and the bed pans are then transferred to a chromium-plated rack, each being numbered to correspond with a bed. Dirty linen is collected in bags, and delivered by a lift outside the building to a trolley which runs on a concrete way to the boiler house. Here the bags are dumped into a steam washer and then are placed in a drying machine, whence they emerge properly disinfected and in a fit state to be sent to the laundry. On each floor is a steriliser for the patients' crockery and knives and forks, and adequate refrigerators for milk and other foodstuffs are provided.

The Operating Theatre.

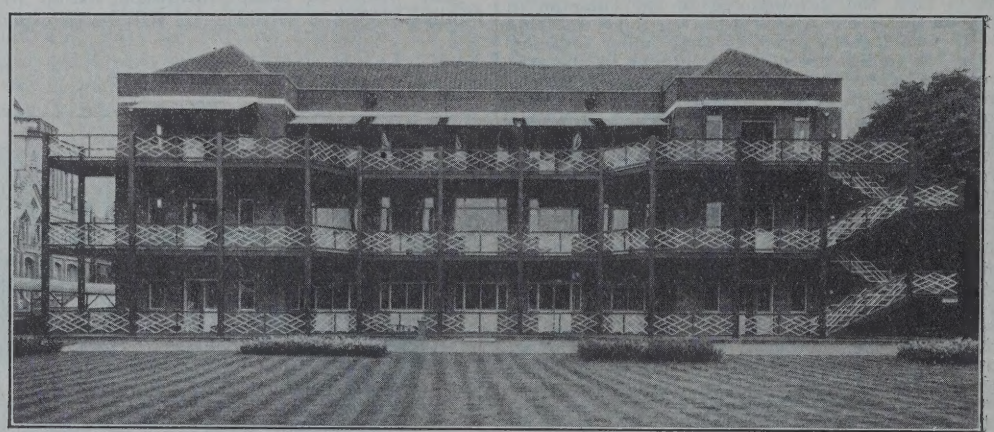
The operating theatre suite is grouped round the large octagonal lobby into which the corridor expands on the first floor of the building. The theatre is provided with modern lighting and equipment, and heated with steam coils let into the north wall; cold filtered air is sucked in from outside. The theatre communicates by means of doorless openings with rooms for dressings and lotions and also with the theatre sterilising room.

On the west of the theatre octagon is the anæsthetic room, on the east the recovery room, whence the patient is wheeled back again to her ward. A retiring room and lavatory and bathroom for the medical staff are near by, and there are also two wall cupboards, one for operating coats and the other for rubber boots. The sister in charge of the theatre has ample dresser and linen cupboard accommodation in her room, the linen being stored on wooden grids, each one of which can be lifted out for sterilising. The motor operating the bed lift has been enclosed in a soundproof chamber on the roof in order to avoid noise.

Kitchens and Boiler House.—No kitchens exist in the isolation block, all the cooking for the patients being carried out in the kitchen of the temporary nurses' home by means of food trolleys which can be kept heated by electricity. After the food containers have been removed to the ward kitchens, whence the food is served to the patients, they are sterilised before being put back in the trolleys for the return journey. Trolleys of a different type convey the food to the 22-bed auxiliary hospital now opened in an adjacent villa to relieve the congestion at Queen Charlotte's.

The isolation block is connected by an underground pipe channel with the boiler house, which is equipped on a sufficiently large scale to cope with the requirements of the future buildings. Automatic electrically driven oil burners supply the fuel for the boilers.

FIG. 2.



Southern aspect of isolation block.

A STUDENT'S AMBULANCE.—Last week the Guild of Undergraduates of Liverpool University presented to the Merseyside Hospitals Council the second ambulance that has been purchased out of the proceeds of their collections.

PUBLIC HEALTH SERVICES

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are 1929 statistics of three metropolitan boroughs, one county borough, one borough, and an urban district.

Name of district and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Lambeth .. (294,400)	15·7	14 9	1·18	1·70	3·1	3·2	68/27	40	3·5
Kensington.. (176,000)	14·4	15·4	0·78	1·60	3·8	2·7	84/27	51	6·3
Bermondsey . (113,800)	19·8	14·5	1·21	1·27	4·6	1·7	71/—	45	2·2
Darlington .. (71,790)	16·8	13·1	1·10	1·16	2·7	2·1	81/36	38	6·6
Swindon .. (62,020)	14·0	11·0	0·43	1·47	2·0	2·0	47/21	30	6·9
Swinton and Pendlebury (34,100)	13·3	13·1	0·85	1·32	3·9	1·3	90/53	48	11·0

Number of stillbirths per 100 live births: Lambeth 3·7, Kensington (notified) 2·5, Bermondsey 2·9, Darlington 5·5, Swindon 5·1, Swinton and Pendlebury 4·6.

Lambeth.

Dr. A. G. G. Thompson reports a satisfactory increase in the attendances at the antenatal clinics. The individual expectant women who attended numbered 2021, whilst the total births for the year were 4622. He is not satisfied with the supervision of the ex-babies, as only 3675 out of at least 15,000 children aged 1 to 5 were brought to the centres. The 29 notifications of enteric fever included a disastrous outbreak, affecting one household, with 12 cases and 3 deaths. Two families of 20 persons inhabited a small four-roomed cottage with a small yard in which there was one w.c. and one water tap for the needs of both families. One of the mothers, a charwoman, developed an illness which simulated pneumonia, was nursed at home, and died after ten days. Two other members of the family were then stricken with typhoid fever, confirmed bacteriologically and removed to hospital. Subsequently nine other members of the two families sickened. In the original case symptoms of typhoid fever appeared near the end, but bacteriological examinations and a post-mortem revealed nothing beyond pneumonia. The only vacant accommodation on the L.C.C. estates was at Becontree and thus out of reach of the many workers who must live near their work. For these the 136 flats to be erected on two sites will afford some relief.

Kensington.

Dr. James Fenton reports that mortality from childbirth showed an increase in the borough. Although 72 per cent. of the expectant women in Kensington received some form of antenatal care, there were 16 deaths of mothers in confinement. Of the 16 women who died, 12 did not receive antenatal attention, and it appears probable that, if they had, five lives might have been saved. In 5 of the 12 antenatal advice would have been of no avail, the only preventive being avoidance of pregnancy. In the other two there was accidental infection at the time of birth, which could not have been prevented by antenatal care. The number of new cases receiving light treatment at the baby clinic and hospital was 150, and the cases of rickets, debility following measles and whooping-cough showed improvement.

Satisfactory work is reported under Section 3 of the Housing Act of 1925, which enables the local authority to carry out repairs in the owner's default and to recover the cost with more certainty than the corresponding section of the 1919 Act. The houses dealt with under this section have numbered 242 and it has only been necessary for the council to do the work in 18 cases, at a total expenditure of £2333. Of this amount, £1339 has been recovered and the remaining £994, with interest, is now being received in instalments. A very good standard of work is being obtained under this section; the owners are responding more readily to notices, and it is believed that this section will prove of considerable value in improving the working-class houses within the borough. Effective action is also being taken to deal with instances of overcrowding and indecent occupation. Thus, during the last five years only 29 summonses have been eventually issued in 371 cases of overcrowding and only two summonses in 318 cases of indecent occupation. This means that 658 families have been able to improve their accommodation without the council having to resort to extreme measures. Another new move has proved beneficial in the relief of overcrowding. When a municipal house is let to a tenant, the medical officer of health writes to the owner of the vacated house, asking him to let to a Kensington family known to be living under overcrowded conditions. A similar method is also being adopted when tenants are moved to L.C.C. and other housing estates. Great improvements have been made in the common lodging-houses for women as the result of private philanthropy.

Of the 22 notified cases of ophthalmia neonatorum one died from another cause and the remainder recovered without injury to sight. Since 1920 there has only been one case resulting in blindness. There were 13 notifications of puerperal fever with 7 deaths, and 41 of puerperal pyrexia with 3 deaths. Dr R. Hobbs, the consultant retained by the council, was called in by local practitioners in 30 cases and visited 4 patients in their homes, while 21 cases of puerperal sepsis were admitted to St. Mary Abbots Hospital under his care.

Bermondsey.

Dr. D. M. Connan's report states that the new patients treated at the solarium numbered 408. A small number of cases of pulmonary tuberculosis showed no improvement. Rickets and malnutrition did well if the attendance was regular, but many mothers do not realise that advanced rickets needs regular prolonged treatment. Nine antenatal mothers improved in health and had normal confinements with healthy babies. Better results than previously were obtained in alopecia. The final result in all the 20 cases sent by the borough council to Leysin has been good and there have been no relapses up to date. Out of 2086 births in the borough 1805 took place either in hospital or in connexion with Guy's Charity. A new scheme is in partial operation under which the fees of approved midwives attending confinements in the home will be paid by the borough council. This will apply to the cases attended by Guy's Hospital and the condition is made that all cases taken by the hospital shall be attended by a midwife. In the past a large number of the cases in the borough have been attended by handy women.

Darlington.

Dr. G. A. Dawson mentions amongst the needs of the town: the proper adaptation of the five centres for the examination of expectant mothers; housing accommodation at about 6s. per week for at least 200 families living in dark court or back-to-back dwellings, an up-to-date swimming bath with continuous

filtration and chlorination; and a modern central slaughter-house and meat store. Artificial light has been installed at the fever hospital and good results are claimed for convalescent debilitated scarlet fever patients. Great difficulty is experienced in finding suitable institutions for the mentally defective. The special school for these children does excellent work, but most of the children on discharge join the ranks of the unemployed. Last year an occupation centre was opened for them. In the poorest quarters of the town several families are living under terrible conditions of overcrowding. The weekly rent of 7*s*. 6*d*. charged for the new corporation "kitchen" houses is a barrier to many hoping to improve their environment. The worst class of house is the most crowded, because the occupants are deterred from moving by the steepness in the ladder of rents. The corporation have built no houses since 1926. Plans are given showing the arrangement of three types of back-to-back houses, housing about 3750 persons. In most of them there is a total lack of wash-house, scullery, and food store accommodation. But for the shortage of houses, many of the "back-to-backs" could be readily converted into "through" houses. Immediate requirements are about 500 new houses to be let at 7*s*. 6*d*. per week. A conversion scheme is in progress but there are still about 5000 privy middens out of 18,500 conveniences. The open-air school with accommodation for 60 boys and 60 girls and the Barnard open-air school for the education of mentally subnormal children have achieved excellent results in their first year's work. The George Dent Nursery School for 80 children from poor homes or suffering from malnutrition has also done well, and the education committee are considering the establishment of other nursery schools in the town.

Swindon.

Dr. Dunstan Brewer thinks the doubling of mental defect during the last 20 years must be accepted as a fact. In October, 1928, the municipal housing estate was brought into the borough. The rule has been adopted to let municipal houses to persons with large families, but Dr. Brewer points out that the payment of the rentals charged means that these families have to go without some of the prime necessities of life. In 1922 the municipality acquired a temporary maternity hospital, in December, 1928, they took over the training school and extern midwifery service from the Wilts Nursing Association, and in 1929 Dr. Sydney Rowlands was appointed consulting obstetrician to the hospital and for other obstetric purposes. The maternity service so established serves the district outside the borough and is worked in coöperation with the county council. During the year there was some trouble in the hospital with puerperal pyrexia. There were 20 cases but many would not have come into the notification category had four-hourly temperature charts not been insisted upon. The hospital was closed from the 11th to the 14th of May. The 40 notifications of puerperal pyrexia were all investigated and included five cases of scarlet fever without a death. They were cases of typical scarlet fever without special feature all in the practice of one midwife, who was eventually proved to be a carrier of Dick's streptococcus. The Registrar-General debits Swindon with six maternal deaths, but Dr. Brewer thinks it is right to include three more as associated with childbirth, making a maternal mortality of 10·4 instead of 6·9. During the last ten years there has been no gap between infancy and school age in Swindon, but it is intended to complete the supervision of the pre-school child by arranging a systematic mental and medical inspection about the beginning of the child's fourth year of life. Dr. Brewer stresses the need for rapid action in the case of illness of a child during the second year of life. As in past years all the stillbirths and the deaths under the age of 20 have been investigated. A complete history is kept at the health office of all children, and it is found by this means that the reliability of death certificates is less than 40 per cent. Dr. Brewer hopes that in time general practitioners will take to using this bureau of information and that by this means diagnosis will be made easier, life will be saved, and many exploratory operations rendered unnecessary. The method adopted in Swindon originated from the teaching of Clifford Allbutt and Charles MacKenzie.

Swinton and Pendlebury.

Dr. H. C. Mulholland says the increased death-rate and infant mortality were chiefly due to the influenza epidemic. Scarlet fever cases numbered 112, 59 less than in the previous year. There were no deaths, and Dr. Mulholland points out that if antitoxin is more used, more cases can safely be nursed at home. Antitoxin is now supplied to doctors, on request, by the public health department. Diphtheria shows a tendency to increase and it is hoped that parents will take more advantage of the immunisation facilities provided at the centres. The high maternal mortality is mentioned as a reason for increased antenatal work. The consultant's report shows that 133 mothers attended this clinic, as against 84 in the previous year. The mothers who attend are interested in getting whatever help they can and the dental treatment provided is becoming more appreciated. Beds at Davyhulme Hospital are available for pregnant women, and there is no difficulty in obtaining hospital treatment for all the puerperal sepsis which occurs in the district. 49 per cent. of the births occurred in two-bedroomed houses, 30 per cent. in houses containing two or more families, 8 per cent. in grossly overcrowded houses. The percentage of total births occurring in miners' families was 17·3, whilst the percentage of infant deaths in the same families was 47·6. The percentage of total births which occurred in labourer's families was 15·6 and the percentage of infant deaths was 23·8. This means that the miners' families had two and a half times and the labourers' families one and a half times their proper proportion of the infant deaths. The sanitary environment of the district has been much improved by the disappearance of the privy middens. Referring to the connexion between damp houses and rheumatism Dr. Mulholland mentions that many of the houses have no damp-proof course and that at least 300 are only fit for demolition.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JULY 5TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 156 (last week 182); scarlet fever, 1754; diphtheria, 1160; enteric fever, 67; pneumonia, 546; puerperal fever, 48; puerperal pyrexia, 95; cerebro-spinal fever, 14; acute poliomyelitis, 8; encephalitis lethargica, 17; continued fever, 1; dysentery, 9; ophthalmia neonatorum, 95. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on July 8th–9th was as follows:—Small-pox, 281 under treatment, 11 under observation (last week 354 and 6 respectively); scarlet fever, 1808; diphtheria, 1996; enteric fever, 26; measles, 385; whooping-cough, 80; puerperal fever, 29 (plus 15 babies); encephalitis lethargica, 122; "other diseases," 11. At St. Margaret's Hospital there were 15 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 27 (9) from measles, 6 (2) from scarlet fever, 9 (0) from whooping-cough, 28 (8) from diphtheria, 56 (11) from diarrhœa and enteritis under two years, and 16 (2) from influenza. The figures in parentheses are those for London itself.

Four deaths from measles occurred at Liverpool, 3 from whooping-cough at Birmingham. Five fatal cases of diarrhœa were reported from Liverpool, 3 each from Birmingham, Nottingham, and Manchester.

The number of stillbirths notified during the week was 265 (corresponding to a rate of 37 per 1000 births), including 42 in London.

CORRESPONDENCE

EFFECT OF RADIUM ON CARCINOMA.

To the Editor of THE LANCET.

SIR,—Mr. W. H. C. Romanis has drawn attention in your last issue to an unusual event following the treatment of a carcinoma of the breast with radium—namely, the appearance of nodules of growth in the skin at the sites of implantation of the radium needles. He suggests that this was due to stimulation of the growth of carcinoma cells by the radium. I think, however, that another explanation is more probable. Mr. Romanis reports that "it was determined to use radium needles of 1·0 mg. each by the usual technique of implantation for 14 days. Thirty needles were implanted," in the breast and lymphatic areas. May I point out, however, that this technique is entirely different from that elaborated at St. Bartholomew's Hospital; this has been published in detail, and is, as far as I know, the only technique which has been extensively used in treating primary carcinoma of the breast. The difference in the technique used by Mr. Romanis lies in the radium content of each needle, the length (presumably, though no detail is given), the total dose, and the time of irradiation.

It has been our practice at St. Bartholomew's to use chiefly needles of 3·0 mg. Ra element each, 4·8 cm. active length, and 0·5 or 0·6 mm. platinum filtration. An advanced carcinoma of the breast requires from 40 to 70 mg. Ra element for the *breast alone*, apart from the lymphatic areas, and the standard time of irradiation has been seven days.

I have always insisted on the importance of using *long* needles in treating carcinoma of the breast owing to the necessity for irradiating evenly the whole area involved, and where possible I have avoided pushing them into the growth itself, the main part of the radium being applied *deep* to it. I have adopted this principle owing to the obvious danger of transplanting carcinoma cells on the ends of the needles, which are necessarily inactive.

It therefore appears to me possible that Mr. Romanis, by using needles which were too short and a total concentration of radium which was too small, may have provided tracks along which carcinoma cells were enabled to grow, many of these cells having been insufficiently irradiated. It is true that the needles remained in position for 14 days instead of the usual seven, but I am not persuaded that implanting 30 mg. for 14 days necessarily has the same therapeutic effect as implanting 60 mg. for seven days. I have always regarded a "milligramme-hour" standard as misleading and dangerous.

If Mr. Romanis would adopt the technique which has been found satisfactory in a large number of cases elsewhere, he may be able to avoid in future the unusual event which he here records.

I am, Sir, yours faithfully,

London, July 11th, 1930. GEOFFREY KEYNES.

To the Editor of THE LANCET.

SIR,—Mr. Romanis's case is more easily explicable, surely, as an illustration of the effects of the setting free of cancer cells in the needle-track, beyond the range of action of the low intensity (1·0 mg.) needles, than as a clear instance of the much disputed stimulation. A definite, but still not very clear, stimulation appears in the connective tissue of some radiated growths—e.g., rodent ulcer and some sarcomata, but there is only very dubious evidence of any real stimulation of malignant cells, in spite of the thousands of cases where it should have been recorded as a result of X ray or radium applications by observers in many countries, and there are findings like those of Nather and Schinz with varied X ray doses on cancer implants in a series of 200 mice, which were completely negative. Without any evidence whatever a "cancer stimulation-dose" was put forward by Seitz and Wintz in their book in 1920, but all the later discussions of the subject by radiologists have tended more and more to relegate the subject to the background, or to take refuge in some "functional-stimulation"—i.e., one not capable of histological proof, in such organs as the thyroid, spleen, and ovary.

I am, Sir, yours faithfully,

J. H. DOUGLAS WEBSTER.

Chandos-street, W., July 12th, 1930.

To the Editor of THE LANCET.

SIR,—The note by Mr. Romanis on this subject in your last issue properly revises the old doubt which has for long given all who use radium furiously to think; but the reported case, to my mind, does not quite carry conviction.

If it be a case of stimulation of existing cancer cells, then it occurred at the point of maximum intensity, immediately about the needle; just where, presuming ordinary screenage, the effect approaches or reaches a destructive or necrotic degree. It seems more likely that the damage done to the tissues at this point has still further weakened the feeble defence presented by normal tissues to the infiltration by the active cancer cell. It is not very uncommon to see nodules form in suture needle cicatrices when cases already fungating are operated upon, and it is certainly rare to find nodules in the much more definite cicatrices of the large platinum needles. Need we blame the irradiation at all? Or is it perhaps the "irritation" of a minute local "burn" that determines the appearance of cancer? This case itself is evidence against the "production" or "causation" of cancer, for the needles implanted in healthy tissues (near the glands) were, it is implied, not affected. It would be a new piece of evidence if a single irradiation "determined" cancer. Here a single irradiation of 14 days was followed by the appearance of nodules "within six months." It can scarcely be that an intensity *less* than that required to secure death, or retrogression, or metaplasia of cancer cells is adequate to "stimulate"; for in that case at *some* distance from every implanted radium unit the lesser ("stimulant") intensity must be reached, and all cases should show new nodules of growth at some point in the body. Is this so? It needs consideration. It is useless, of course, in these problems to appeal to the pure physics of radio-activity. The phenomena of acquired radio-resistance are alone enough to settle that. But what are the unknown factors in this problem? Mr. Romanis's case is suggestive indeed, but, without any intention of quibbling, I would ask, is it really suggestive of "stimulation?"

I am, Sir, yours faithfully,

E. ROCK CARLING.

Brook-street, W., July 15th, 1930.

THE WIDAL TEST.

To the Editor of THE LANCET.

SIR,—Dr. Eustace Thorp's experience with the Widal test, published in your issue for June 7th (p. 1235), corresponds so closely to what used to be my own experience, that I cannot help commenting on it. It is just this "negative Widal" in what afterwards turned out to be sure cases of enteric, which has brought the "Widal" into disrepute with the majority of clinicians in South Africa, and the lack of respect for "laboratory findings" in general which is so noticeable out here is in large measure due to the apparent failure of laboratories to reach satisfactory results with this supposedly simplest of serological tests. Of course, the clinician who only labels such of his cases "typhoid fever" as on one or other occasion have given a positive "Widal," and ignores other cases, will, when he goes through his records of typhoid patients at a later date, observe a very satisfactory incidence of positive tests, and this all too common error in logic still obscures the shortcomings of the ordinary "Widal" in many quarters. Dr. Thorp did just the opposite, he followed up the cases where the "Widal" was negative and found them to have typhoid fever. Unfortunately, he does not give particulars about the nature of the "Widal" employed.

When, in 1922, by similar methods I arrived at the identical conclusion that the "Widal" is not much use for the diagnosis of typhoid fever, I replaced this test by a complement-fixation method. This proved highly satisfactory, since it brought the percentage of positive reactions in first tests on sure cases of typhoid from about 50 with the Widal to 96 with the complement-fixation method. These findings were ignored, or held to be applicable to South Africa only. It was only when A. Felix, in a series of papers, demonstrated (1) the importance of O-agglutination; (2) the fact that and the reasons why O-agglutinins cannot adequately reveal themselves through an ordinary "Widal"; (3) the practical identity of O-agglutinins and complement-fixators; and (4) the peculiar sensitiveness of a particular strain of typhoid bacilli for O-agglutinins, that the good results achieved with complement-fixation could be brought into line with all other findings and the whole position cleared up. In the past few months THE LANCET has given a good deal of publicity to this new orientation in serological tests for typhoid fever.

It has now become possible to replace the complement-fixation test, with its drawback of difficult execution, by an agglutination test again, but this time with due regard for the formerly neglected O-agglutination. If we must go on calling this a "Widal," let us then speak of a "Felix-Widal." My results with this method were published in the February issue of the *Journal of Hygiene* (p. 380). Further experience during another typhoid season completely bears out the conclusions I there recorded: that it is possible to diagnose serologically practically every case of typhoid fever at the first blood examination, provided due attention is paid to O-agglutination. For the technique I must refer to original articles, more especially that by Dr. Felix in THE LANCET of March 8th, 1930, p. 505. I admit the difficulty of using live suspensions of bacilli for the tests, but here the Oxford standard laboratories have come to the rescue by placing special O-sensitive killed suspensions on the market.

There is, therefore, nowadays no excuse for a "negative Widal" in a case of typhoid fever. But as long as laboratories will go on using any old carbolised suspension of typhoid bacilli for agglutination tests and call that a serological diagnostic method, so long there will be dissatisfaction among clinicians, many diagnoses will be missed, many carriers will remain undetected, and the incidence of typhoid fever will not decrease.

I am, Sir, yours faithfully,

ADRIANUS PIJPER.

Pretoria, South Africa, June 25th, 1930.

THE INTERPRETATION OF DENTAL RADIOGRAMS.

To the Editor of THE LANCET.

SIR,—Medical men have for many years known and proved to the satisfaction of all concerned that localised systemic infections and intoxications could be due to dental sepsis. Until recent years these opinions were strongly opposed by the dental profession, and it is only after years of persistent repeated demonstrations that the dentists have been brought to realise the importance of dental sepsis. Even to-day many dental surgeons of repute will not admit that dental sepsis has any influence on the health of the individual, and as a consequence ignore obvious naked-eye or radiographic evidence. Radiologists have provided the medical profession with definite and visible signs of obscure dental sepsis, the appearance of which can readily be learnt by any interested person. Yet the leading article of THE LANCET of July 12th, and the series of articles by Mr. Bowdler Henry dealing with this subject, suggests that the only person capable of giving an opinion on a radiograph is a dentist, and that the opinion of a physician, whether a radiologist or not, is of little value, as shown by the following statement: "Among dental surgeons it is a commonplace of conversation, not often expressed in print, that radiographic reports in general have little value." Further, Mr. Henry, although he has gone to some pains to illustrate many of the radiographic appearances of pathology of the teeth—which has been done quite as ably on many former occasions by radiologists—for some reason or other thinks that the medical man has not, or is not capable of acquiring, the knowledge of these appearances and of giving an opinion on the radiographic evidence of dental sepsis. I quite admit that the possession of an X ray equipment and the production of radiograms does not signify that the possessor has taken the trouble to learn the anatomy and pathology of the part or its radiographic appearances, but it must be obvious to most that the specialising radiologist is much more likely to possess the ability to produce a good radiogram and the knowledge to interpret its appearances than the busy dental practitioner who is provided by the manufacturers with a "fool-proof" apparatus.

The editorial article states: "Here lies the importance of studying the minute and intimate bone structure, which is only possible in a set of radiograms of high technical quality," but even Mr. Henry has had to call in the help of Messrs. Kodak, Ltd., in producing his illustrations. Mr. Henry points out that "A radiogram requires careful study under proper conditions of illumination and magnification by one who has knowledge of the structure of the teeth and jaws." Yet every radiologist is called upon from time to time to radiograph the teeth of patients which have been radiographed a short time

before by a dentist, and nothing reported as to the presence of sepsis, either to the patient or to his doctor, and finds definite evidence of old-standing septic lesions which have been missed or ignored by the dentist. One wonders why, if these obvious lesions are so ignored, the dentists takes radiographs at all, and one is forced to think they have taken the advice of a well-known text-book on dental pathology and therapeutics, which advises dentists to take their own radiographs because "such profits as may accrue are his."

In Mr. Henry's article in your issue of July 12th (p. 95) the following astounding case is published with illustrations :—

"A patient of 60 years with a tooth showing a chronic abscess enjoyed good health for many years, annual radiograms showing the area to be of constant size and demarcation. A final radiogram showed the septic area to have broken bounds, the outline of the cavity becoming blurred and extending on one side. This was followed shortly by cardiac disturbance of toxic origin, which has not recurred since the tooth was removed."

The legend to the illustration reads as follows :—

Fig. XVI. (A, B, and C).—Showing chronic abscess G, clearly defined in 1926. In 1927 it was rather larger but still well defined within a smooth white wall. In 1928 the abscess has spread to the neighbouring tooth and has a hazy irregular wall."

And on page 96 Mr. Henry states a well-known fact :—

"The longer septic teeth remain in the jaw the less chance the patient has of complete recovery from infection after their removal."

That an abscess of this size should have been detected in the patient in 1926, allowed to remain, and annual radiographs taken so as to watch the progress until it involved other teeth, and the patient developed cardiac disturbance of toxic origin, is almost incredible. Yet this kind of "animal experiment" is frequently being detected by radiologists—no wonder Mr. Henry is opposed to the doctor sending his patients for radiographic examination first.

I have recorded the death of a friend, aged 36, in whom I found two septic teeth and advised extraction, but the advice was ignored by the dentist, and several months later, owing to an acute flare, the teeth were extracted and death resulted from septicæmia within a week. Mr. Henry refers to the fallacies of the radiograph, and suggests that the doctor or radiologist mistakes anatomical foramina for apical abscesses, which may result in a healthy tooth being extracted. I have repeatedly shown that the more important fallacy is made by the dentist mistaking a large apical abscess for a normal antrum or foramen, and a source of chronic sepsis remaining undiscovered until a physician has insisted upon an independent opinion from a radiologist. There are dental surgeons, no less enlightened than those referred to by Mr. Henry, who still send their patients to radiologists for an X ray examination and report. There is never any difficulty in such coöperation, and the radiologist is always prepared to take additional radiographs to clear up any doubtful point. These dental surgeons have the support of the patient's doctor and the radiologist in carrying out any extraction which may be deemed advisable, and he never appears in the unfavourable position seen so often, when the procedure is adopted, which the leader and article referred to advocates.

For these reasons I believe that the patient, dental surgeon, and the doctor are best served when an independent unbiased opinion is obtained from a competent radiologist on the radiographic appearance of the teeth.

I am, Sir, yours faithfully,

JAMES F. BRAILSFORD, M.D.

Birmingham, July 14th, 1930.

*** Mr. Henry acknowledges the help of the Kodak Company in the reproduction, *not* in the production, of his radiograms.—ED. L.

STERILISATION OF THE UNFIT.

To the Editor of THE LANCET.

SIR,—We have read with interest the valuable article on the above topic by Dr. F. A. Gill in your issue of June 21st. We would point out, however, that sterilisation for other than therapeutic reasons can be construed as illegal in this country at present. In fact, the law upon the subject is so ambiguous that it would be difficult for the Board of Control to give its sanction to a sterilising operation performed with any other aim than that of benefiting the health of the subject operated on.

With the object of getting eugenic sterilisation legalised a committee has been formed from the Eugenics Society, the aims of which have been set out in a pamphlet.[1] The views of this committee coincide closely with those of Dr. Gill in all except one respect. Dr. Gill says: "If every certifiable mental defective had been sterilised 20 or 30 years ago it would have made little appreciable difference to the number of mental defectives existing to-day."

We believe Dr. Gill to be in error in this supposition. One of us has shown[2] that if all the defectives in the community could be prevented from having children the effect would be, even on the most unfavourable genetic and social assumptions with regard to defectiveness, to reduce the incidence of mental defect by as much as 17 per cent. in one generation.

We are, Sir, yours faithfully,

C. P. BLACKER, R. LANGDON-DOWN,
R. A. FISHER, F.R.S., J. A. RYLE,
R. A. GIBBONS, C. COLLYER.

20, Grosvenor-gardens, London, S.W.1, July 12th, 1930.

GERSON DIET FOR TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—Perhaps you will allow me to add a few words to your interesting editorial note on the above in your issue of June 28th. A few months ago I had an opportunity of studying the Gerson diet, and of observing the results of the treatment in a wide range of medical disorders in Gerson's Clinic at Cassel, also in the Surgical Clinic of Prof. Sauerbruch, of Berlin University, and in other German institutions in which a special kitchen had been recently installed for this dietetic system. The results observed confirm the very favourable impressions of the great value of this treatment recorded by these authors, and confirmed by numerous independent clinicians in Germany in the past two years.

The very favourable results of the diet therapy recorded by Prof. Sauerbruch in the past few years apply specially to the treatment of surgical tuberculosis as it affects the skin, bones, joints, and lungs. The dietary system employed by Sauerbruch, while based on the Gerson principle, is somewhat

[1] Obtainable from The Secretary, Eugenics Society, 20, Grosvenor-gardens, London, S.W. 1.

[2] Fisher, R. A.: The Elimination of Mental Defect, Eugenics Review, 1927, xvi., 11.

different from the strict Gerson régime; it is based on modifications devised by Prof. Herrmannsdorfer of the surgical department of the Charité. Gerson, however, claims that his method has equal application, in a wide range of common medical disorders, such as arthritis, cardiovascular degeneration, disorders of the nervous system, and other conditions.

In view of the profound importance of the subject, it is interesting to know that arrangements have been made for the translation of Gerson's book.

I am, Sir, yours faithfully,

CHALMERS WATSON, M.D.

Edinburgh, July 10th, 1930.

NOISE IN HARLEY STREET.

To the Editor of THE LANCET.

SIR,—I have no doubt that every specialist in Harley-street would unhesitatingly agree that the use of the mechanical drill for road repairs, immediately opposite a hospital, is bad for both patients and staff, but I believe I am correct in stating that in their protests against the use of this fiendish device within a certain radius the hospitals have so far "ploughed a lonely furrow." The correspondence in your columns illustrates how necessary personal experience of a nuisance sometimes is to ensure a proper appreciation of it, and I hope that "Harley-street" will now make its voice heard and its influence felt with the object of ensuring that the use of the drill will be forbidden within, say, one hundred yards of any hospital. I am, Sir, yours faithfully,

RALPH B. CANNINGS,
Secretary, City of London Maternity Hospital.

July 11th, 1930.

TREATMENT OF VENEREAL DISEASE IN THE EAST END OF LONDON.

To the Editor of THE LANCET.

SIR,—Your editorial note on the treatment of V.D. in this hospital needs a small correction for the sake of accuracy. You write that the annual grant contributed by the L.C.C. towards the work of the clinic carried out under the auspices of the hospital was "withdrawn."

This is unintentionally misleading. The L.C.C. were quite willing to go on with the agreement and to continue the grant, but the hospital came to the conclusion that it would be a better arrangement to lease the premises at an agreed rent, and to leave the management entirely to the L.C.C. under their own chosen head, rather than to continue a sort of joint management.

I am, Sir, yours faithfully,

KNUTSFORD.

London Hospital, Whitechapel, E., July 9th, 1930.

A PROTEST FROM REGISTERED NURSES.

To the Editor of THE LANCET.

SIR,—The Royal British Nurses' Association and the British College of Nurses take strong exception to the following advertisement which appeared in the *Nursing Mirror* of June 14th last:—

"Will those nurses who have failed in their final State or hospital examinations, either this or last year, and who have left or are leaving their training school, communicate their name and address to 2725, "The Nursing Mirror," 24, Russell-square, London, W.C. 1, when they will be offered posts with a salary equal to that of a trained certificated nurse."

This advertisement is calculated to cause injur to the members of the nursing profession because i ignores the legal status of that profession, disregard the value of a minimum standard of qualification a established by the State, undermines the economi privileges of the nurses, and fails to protect the sic from unqualified and dangerous attendants. Th Royal British Nurses' Association and the Britis College of Nurses beg to enter the strongest protes against such an advertisement.

We are instructed to forward to you this protes for publication.

We are, Sir, yours faithfully,

ISABEL MACDONALD,
Secretary, Royal British Nurses' Association.

ALICE STEWART BRYSON,
Secretary, British College of Nurses.

194, Queen's Gate, London, S.W., July 12th, 1930.

TREATMENT OF DELIRIUM TREMENS.

To the Editor of THE LANCET.

SIR,—I am interested in this subject, and shoul like to see a full account of the remarks by D E. F. Wills. However, your annotation in TH LANCET of July 12th states that the main questio with which he dealt was whether the sudden witl drawal of alcohol is a factor in the onset of deliriu I gather that Dr. Wills holds: (1) that delirium more likely to manifest itself when alcohol has bee abruptly discontinued; (2) that in cases associate with shock, the real factor determining the sympto (delirium) will be found to be the withholding alcohol.

The assigned causes of delirium tremens are variou Yet I suppose that we all agree that the commone cause is the taking of alcohol to excess. My experien with inebriates may be interesting in this connexio and I briefly set it before your readers for what is worth. I have been medical superintendent inebriate reformatories, 1903–12. During that perio I had under my care upwards of a thousa inebriates, and a large percentage of these were se to me direct from the courts, and, therefore, fre from a "bout" or a "soaking." In every case alcoh was absolutely barred from the date of admissio In not one single instance did delirium treme develop.

I therefore hold that the sound treatment for t inebriate is to stop the alcohol, and soothe or stimula according to the condition of the individual.

I am, Sir, yours faithfully,

DAVID MCVEA FLECK.

Stapleton, Bristol, July 14th, 1930.

*** We understand that Dr. Wills's paper will appe in the October issue of the *Journal of Inebriety.* ED. L.

BRISTOL GENERAL HOSPITAL.—Last year t excess of ordinary expenditure over ordinary inco was £10,544, and it has again been necessary to u nearly all the free legacies received during the year make good the deficit. The president, Sir Vernon Wi and his four sisters have contributed £20,000 to found "George Alfred Wills Endowment Fund" towards t maintenance of the Susan Britton Wills Nurses' Fund. new children's ward, a new male ward, and a new operati theatre are being provided at a cost of over £17,000. Th were 4671 in-patients, who cost £8 10*s.* 10*d.*, and stayed average of 19·31 days. The new out-patients numbe just under 31,000.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

ON July 10th, in the House of Lords, the Royal Assent was given to 38 Acts, including the Mental Treatment Act.

WORKMEN'S COMPENSATION (SILICOSIS) BILL

On the question that Clause 1 (which extends the Workmen's Compensation Act, 1925, to industries involving exposure to asbestos dust) stand part of the Bill, Mr. SHORT, replying to questions by Mr. C. Williams and Major Braithwaite, said the extension of the Act of 1925 to asbestosis was due to the report of an inquiry submitted to Parliament in March, 1930, that there was grave danger of workers in the asbestos industry contracting fibrosis of the lungs, culminating not merely in disablement but in death. Fourteen deaths were recorded, and the incidence of the disease affected one in eight of those employed, a figure that only applied to those who were actually in employment at the time when the examination took place. Roughly 2000 people were thus employed. The employers, who believed that the provisions of this Bill were on the right lines, and the Trade Union Congress, representing the industries and workers concerned, were also agreed.

The clause was added to the Bill.

MEDICAL ARRANGEMENTS.

On Clause 2 (which deals mainly with the coördination of the medical arrangements in connexion with compensation schemes),

Dr. VERNON DAVIES, having moved and later withdrawn an amendment confining the operation of the clause to groups of industries and processes in which silica or asbestos is used industrially, moved after the word "coördinating" ("coördinating the medical arrangements") to insert the words "or altering." He said that this amendment hung very considerably on another which he had on the Order Paper providing that the medical staff concerned with the diagnosis of silicosis, and particularly of asbestosis, should be full-time medical officers in the employment of the Home Office. His reason for suggesting that was that the diagnosis of silicosis and asbestosis required men of great experience and expert knowledge. There were not many of those men in the country at present, and when they considered that in the future these cases coming up for compensation would be open to very grave doubt as to whether the state of health was really due to the condition of the lung, it was essential that the medical men who examined and reported on this scheme should be absolutely expert. The diagnosis of silicosis was easier than that of asbestosis, inasmuch as it can be done by X ray photography and did not require the difficult laboratory procedure.

Dr. Davies proposed that the Home Office should have a staff expert in the diagnosis of these diseases; whole-time Government servants, or at any rate medical officers "who could not be got at."

Mr. SHORT said that there were few doctors in the country who could diagnose these diseases, and when the hon. Member wished to do away with the employment of part-time medical officers there were two points to be dealt with. There was the periodical medical examination of workers employed in the industry which would be carried out by the medical board—whole-time officers. Supposing the periodical examination took place at the factory they could not expect the members of the Board to go back whenever an employer was taking on a new employee. What had been done—and it had proved effective—was to utilise the services of the local tuberculosis doctors for the initial examination.

Dr. DAVIES said that those officers were State officers.

Mr. SHORT said that was so, but they were not answerable to the Home Office in the same sense as the medical boards and members of the medical panel. If he accepted in its entirety the hon. Member's amendment the Home Office would not be able to use a part-time medical man. That would be fatal. But he did not think there was much between them in this matter. They recognised that if they were ever going to deal with this dread disease they must have experts who would have at their disposal all the latest machinery and knowledge of medical science. Therefore the Department did propose to ensure the appointment of full-time medical men, and they possessed sufficient statutory powers for the purpose. At the same time they would not like to lose the services of part-time medical officers.

Colonel FREMANTLE differed a little from Dr. Davies, but was, generally speaking, in favour of the general practitioner as the basis of all work because he had a general sense of proportion. It was useful to have medical boards and consultants from pathological laboratories and hospital staffs, but it was all the more important to have men in general practice who knew how the expert view fitted into the whole. That was one of the dangers of the divorce between the different Government departments in regard to their medical branches. There was need for some controlling committee for medical affairs which would bring the medical department of the Home Office into contact with the Ministry of Health and of half a dozen other departments of the State which had big health departments. He would prefer to leave this matter in a rather fluid state, hoping that the Home Office would become less and less departmentalised in regard to medicine, and would use more and more the services of men working under other departments and in other capacities. He hoped that that would mean that the Home Office, with its very excellent medical department, would devise the scheme in an elastic way in order not merely to meet the necessities of this Bill but to fit in with the constantly increasing number of measures which must be passed in connexion with industrial health.

After further discussion Mr. SHORT said that the choice of medical officers for the work would be open to the whole profession, who would apply to the selection board at the Home Office. He thought periodical examinations might take place yearly or at intervals of two or three years on the assumption that there would be two or three additional panels; that would mean that it would cost £5000 or £6000, making the total cost, roughly speaking, from £14,000 to £15,000, towards which a Treasury grant would help.

Dr. DAVIES admitted that there was very little between the Under Secretary for the Home Office and himself, and withdrew the amendment when the committee adjourned.

FEES AND OFFICIAL SALARIES.

The Bill was further considered by Standing Committee A on July 10th. Mr. CECIL WILSON was in the chair.

Mr. C. WILLIAMS asked how much of the official salaries and expenses would come out of the fund.

Mr. SHORT said the resources of the fund would be derived from fees paid by employers for periodical examinations, and there would also be a certain sum to be derived from fees for the examination of workpeople. When a workman sought a certificate it was intended to be provided within the scheme that he should make some contribution for the certificate. In addition there would be a contribution from the Treasury. The Treasury contribution would augment the fund, out of which would be paid all the medical expenses and so forth. The contribution of the Treasury would not be an independent fund, but

would be linked up with the fund derived from the fees. It was estimated that the contribution from the Treasury would be somewhere in the neighbourhood of £1000. The chief medical officer would receive £1100, and other members of the Board would receive salaries varying from £750 to £900, with a small allowance of £50 to each of the senior members of the three panels. When they linked up, as they hoped to do, the existing arrangements under the refractories and sandstone scheme with this newer scheme, and made it more national, these matters would be subject to variation. Whether the dependents would have to pay for a post-mortem examination had not yet been decided. The Home Office had undertaken to appoint an advisory committee, and to consult all the interests concerned with a view to securing the largest measure of agreement between employers and representatives of the workers. Subsequently the Home Secretary would draw up rules and regulations setting out the nature of the fees in respect to all these matters. These rules and regulations would be submitted to Parliament, which, if it chose, could annul them.

Mr. HOLLINS moved an amendment providing that no fees should be charged to a workman for any examination except in the case of a workman who made an application to the medical board for an examination, when the board, if they considered the application a frivolous one, might require the applicant to deposit the prescribed fee, not exceeding five shillings, the deposit to be refunded to the applicant if his claim was upheld by the board. He said he was rather startled by the statements of the Under Secretary. Some portion of the cost of the medical board would be placed on the workpeople. His amendment sought to limit that burden. Claims for compensation in the case of industrial diseases ought to be placed upon an entirely different basis from accidents.

A long debate ensued on this amendment, which was withdrawn, and Clause 2 was ordered to stand part of the Bill.

On Clause 3 (Short Title and Construction) an amendment moved by Mr. HACKING to include the word "asbestosis" in the title of the Bill was accepted by Mr. SHORT and agreed to.

The committee stage was concluded, and the Bill, as amended, was ordered to be reported to the House.

SLUM CLEARANCE BILL.

The House of Commons considered the Housing (No. 2) Bill on Report on July 8th.

Mr. JOWETT moved a new clause providing that the dimensions of houses built for rehousing purposes under this Act should not be less than the minimum requirements laid down by Section 2 of the Housing Act, 1923. He said as far as he could gather there was nothing in this Bill requiring a minimum size for the houses to be built under it. That was a most unfortunate omission in a Bill which based the State subsidy on the number of persons to be accommodated and not on the house itself. In the Act of 1923 a self-contained house of two storeys must not have a superficial area of less than 620 superficial feet, and a self-contained tenement must not contain less than 550 superficial feet. As far as he could estimate, a single-storey house with 620 superficial feet would allow of there being only three rooms of 14 feet square, with the necessary pantry, and accommodation for other purposes. If an extra bedroom had to be included, as would be necessary with a family of five, there must be a skimping of the size of the rooms beyond what was desirable or sanitary. That would be still more the case with tenement dwellings.

Mr. KINLEY in seconding the clause said that now they were making a beginning in dealing with the worst class of property they must not set up a low standard.

Mr. GREENWOOD, while sympathising with the amendment, said that, in the case of slums, minimum and maximum requirements must be disregarded, while in the case of very poor people every additional room not required was an unnecessary addition to rent.

When no additional bedrooms for children were required, he said, they made provision for smaller houses with lower rents, more conveniences, and less household work. Local authorities already had their by-laws dealing with the point of space per room, and it would be descending to very considerable detail to specify in an Act of Parliament the space per room, because that should depend upon the use to which a room was to be put and the number of persons who would occupy it.

Mr. ERNEST BROWN said he was sure that housing reformers throughout the country would read with dismay the defence made by Mr. Greenwood for turning down this clause.

Mr. HARRIS said, in this clause they ought to have it made clear that some standard of housing would be required. It was not a mere matter for the local authority, because the State and the local authorities were partners in this matter. There was a constant temptation to local authorities to build cheaper houses, but he was convinced that the local authorities ought not to attempt to build poor stuff to meet the needs of the poor. That would perpetuate slums. It would be a very bad thing for the country if the purpose of this Bill was to provide a lower standard than that provided in the Act of 1923.

Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that they were demolishing the slum houses and rehousing every single person, and that it might surprise Members to learn that in slum areas there frequently were very few children but many lone persons. The new clause did not alter the size of the rooms, but only the size of the houses.

Sir THOMAS WALKER said that the House would not be satisfied unless it had an assurance from the Minister of Health that provision would be inserted in the Bill to preserve a reasonable standard of size for the family house and a reasonable minimum of air space in the rooms.

Mr. GREENWOOD said that if the House would be satisfied that in so far as they built houses of the type built under the 1923 and 1924 Acts with elasticity at both ends, that standard should be maintained, he was prepared to insert an amendment in the House of Lords. That amendment would provide that in all these clearance schemes the two- and three-bedroom houses would conform to the standard of the 1923 and 1924 Acts.

Mr. JOWETT said in view of the promise given by Mr. Greenwood he would withdraw his clause.

The clause was by leave withdrawn.

On Clause 17 (Power of local authority to require repair of insanitary houses),

Mr. GREENWOOD moved an amendment providing that action by a local authority under the clause as regarded repairs to houses, and under Clause 19 as regarded demolitions, might be taken upon consideration of an official representation or a report from any of their officers, or other information in their possession.

The amendment was agreed to.

On Clause 27 (which lays down special conditions with which the local authority is to comply),

Dr. DAVIES moved the addition of the following paragraphs:—

(*c*) That the rents applicable to the houses shall be the same as those charged for similar houses provided by the local authority, or if there are no similar houses then as may be in proportion to those charged for other houses in the neighbourhood, having regard to size, materials, and amenities, but such rents shall be subject to rebates in the case of individual tenants as hereinafter provided;

(*d*) That rebates from the rents of the houses may be granted to individual tenants in such manner and on such terms and conditions as the local authority may think fit, provided that the total amount of such rebates does not exceed in any one year the total amount of the rent pooled formed as hereinafter enacted;

(*e*) That there shall be paid by the local authority in each year into a rent pool a sum equal to the difference between the rents applicable to the houses in accordance with this subsection.

Lieut.-Colonel FREMANTLE seconded.

Miss LAWRENCE said she must ask the House to reject the amendment. Under this Bill they were giving local authorities an additional subsidy, all of which must be passed on as reduced rents to the tenants. The variety of circumstances that the local authorities would have to take into account were so great that they must be allowed to carry out experiments in the matter, each suiting the case to its own needs.

Mr. CHAMBERLAIN regretted that Miss Lawrence had taken up so rigid an attitude. There was nothing in the Bill to prevent a local authority making a flat rate reduction on the rents of these houses, which would defeat the purposes of the Bill.

The amendment was negatived by 220 votes to 120.

On Clause 49 (which deals with official representations),

Dr. DAVIES moved an amendment providing that in urban districts with more than 10,000 population [against the 20,000 in the Bill] the county medical officer should not make representations to the local authority without consulting the district medical officer.

Miss LAWRENCE accepted the amendment, which was agreed to.

The Report stage of the Bill was concluded.

THE THIRD READING.

On the motion for the third reading of the Bill,

Sir KINGSLEY WOOD said that the vital question was whether the increased subsidy which the Bill offered would in fact provide houses at lower rents for the poorer paid members of the community. As a matter of fact, the rents of the Wheatley houses, notwithstanding the larger subsidy, were no less than the Chamberlain houses with the smaller subsidy. Therefore the Government were doing nothing for the poorer paid workers of the country. In the provisions for differential rents the Government were placing a most unfair burden on the local authorities.

Mr. GREENWOOD said he was glad that although the Bill had been improved in minor particulars its principle still remained. The Bill was not an alternative to the Wheatley Act; it was complementary to it, and was intended to deal specifically with a problem which hitherto had been ignored. That problem could not be dealt with merely by putting up more houses; it could only be dealt with by the double policy of destruction and reform of slum areas on one hand and the building of new houses on the other. He did not pretend that slums which had been in the making for 400 years would be destroyed in a few months, but the Bill was the first comprehensive measure designed to deal with this particular problem in a new and more effective way. He appealed to the local authorities to make the maximum use of the measure.

The Bill was read a third time.

ROAD TRAFFIC BILL.

HOSPITALS AND MOTOR ACCIDENTS.

On Thursday, July 10th, the House resumed consideration of the Road Traffic Bill as amended in the Standing Committee.

On Clause 10 (which deals with the rate of speed),

Colonel ASHLEY moved an amendment to empower the Minister of Transport, by regulations to be approved by resolutions of both Houses of Parliament, at some future time, if he thought fit, to vary the speed limit laid down in Schedule I. for commercial cars and heavy vehicles, but not to impose a speed limit on any vehicle in the case of which no speed limit was provided by the schedule.

Mr. MORRISON (Minister of Transport) said the proposal was sensible and rational in view of the possibility of changing conditions in the future, and he would accept it. His attention had been drawn by Mr. Harris, on behalf of the London County Council, to a doubt in their minds as to whether in the new circumstances it would be possible to make a variation in the speed limit in the case of the fire brigade and the ambulance services. He was advised that that power would remain. Any change necessary could be made when the Bill reached the House of Lords.

The amendment was agreed to.

On Clause 36 (requirements in respect of policies),

Major HILLS moved to leave out Subsection 2. He said that the Bill compelled the owner of a motor-car to take out an insurance policy covering him against third party risks, and it was provided in the subclause with which he was dealing that where payment was made on such a policy to a third party there should also be paid by the authorised insurers the expenses reasonably incurred by a hospital in affording treatment to an amount not exceeding £25 for each person treated. To call upon a motorist to pay by means of an insurance policy to a quite outside person money which he was under no legal liability to pay was the wrong remedy for the evil.

Colonel ASHLEY said that the hospitals wanted this provision, and that they were perfectly satisfied with it. Why should Major Hills know better than the hospitals?

Major HILLS said he objected to the provision because the hospitals were getting too little.

Colonel ASHLEY said he did not think that any answer to that objection was required. Lord Luke in the House of Lords had painted a very gloomy picture with no unduly heavy brush of the position of hospitals on the great arteries of traffic. The strain was severe on them, and the local population were excluded from their own institutions.

Mr. MORRISON said that the Government proposed to leave the decision in this matter to an entirely free vote of the House. He appreciated the need of the hospitals for money, and personally he had always taken the Socialist view that the scramble of the voluntary hospitals, which ran a public service, for voluntary contributions was a degrading business, and that the hospitals of this country ought to be run as a public health service. The motorist and the insurance company both had a right to be considered. This subsection was alien to this part of the Bill, whose sole object was to end, or substantially to end, the scandal of persons being injured or killed and not being able to get compensation. The objection to the subsection had been summed up in the House of Lords by Lord Atkin, who pointed out that a provision under which a policy of insurance involved a direct obligation upon an insurance company towards an unnamed hospital would be contrary to the whole principle of insurance, and that being so it was hardly to be wondered at that the subsection bristled with difficulties and anomalies. It was illogical, would be haphazard in its effect, and so extremely awkward to work in practice that it might be largely ineffective. It proposed to make provision for payment to hospitals only in certain cases. He agreed that the hospitals were burdened as a result of motor accidents, and he sympathised with them. But that was a problem of hospital finance which ought to be faced accordingly. The greatest difficulty in the subsection was that the liability for payment to the hospital depended on the fact of treatment in a hospital coming to the knowledge of the insurance company. There was no obligation to pay if it did not come to the knowledge of the insurance company, or of the owner of a vehicle in cases where a security bond had been taken out. It was obviously undesirable that a statutory right to payment should be based on such very uncertain foundations. The hospital authorities would have to find out whether the injured person in fact received compensation, and if so whether the motorist responsible was insured or was covered by a security bond, and the name of the insurer, if there was one, or in cases where a security bond had been taken out the name and address of the owner of the vehicle.

Their chances of finding out the name and address of the insured party would depend largely on whether evidence of compliance with the provisions of this part of the Bill was produced at the time when the accident occurred or not. Finally, they would have to find out whether the fact of treatment had been brought to the notice of the insurer, or to the owner of the vehicle in a case where a security bond had been taken out. In the Local Government Act, 1929, it was laid down that a person receiving treatment at a municipal hospital under the Act should pay according to his ability. That was honest and above board. If the voluntary hospitals had arrived at the point when they could no longer run on a voluntary basis it was not unreasonable for those hospitals to say, as municipal hospitals did, if their trust deeds would allow it, that if patients could afford to pay they should pay what they could afford for their treatment. That would have been logical and fair all round, but he could not say that this was fair. This agitation had been very fully conducted. He sympathised with those who for reasons which they all understood were anxious not to vote in such a way that they might be accused of voting against the interests of hospitals, but he would take that risk. He knew the pressure that had been brought to bear, he knew the honourable sentiment which existed in the matter, and he knew that the insurance companies had taken very few steps, if any, to put the other side of the case and defend their interests.

Dr. MORRIS-JONES said that the voluntary hospitals were going through a very difficult time, and he felt sure that the House would not deprive the hospitals of the very small amount of money which they would get under this Bill.

Dr. FORGAN said that the voluntary system of conducting hospitals, useful as it had been in the past, was now out of date, and the great majority of the hospitals were nearly bankrupt. The amount of financial support which the Bill would bring to them was very slight, and he entirely disagreed with the view of Dr. Morris-Jones that the House should do anything to subsidise a system which would very soon cease to exist.

Sir H. NIELD said surely motorists could pay a few shillings more on their policy in order to give some recompense to the hospitals who were striving so hard to make ends meet.

Mr. HOLFORD KNIGHT said they were not concerned with the present condition or the future conditions of voluntary hospitals, or with the merits or demerits of the voluntary system. In the main he confessed that he shared the view of the Minister on that subject, but that was not the issue in this instance. It was common knowledge that in recent years very heavy drains had been made upon the resources of the hospitals in respect of motor accidents. As the Bill made provision for some of these cases, as an act of justice to the hospitals he asked the House to resist the amendment.

Sir J. LAMB said this was in no sense an effort to obtain funds for the hospitals. It was merely an attempt to obtain payment for certain services which were forced upon the hospitals.

Mr. BEN GARDNER said he objected to a clause which permitted people to be compulsorily taxed in order to give funds to certain associations without having any voice in the management of those associations.

After further debate,

Major HILLS said he always had a great respect for the opinions of the House of Commons. He was persuaded which way the decision would go, and therefore he asked leave to withdraw his amendment.

The amendment was withdrawn and the further consideration of the Bill was adjourned.

HEALTH SERVICES IN SCOTLAND.

On Monday, July 14th, the House of Commons considered in Committee of Supply a vote to complete the sum of £2,791,592 required for the salaries and expenses of the Department of Health for Scotland. Mr. W. ADAMSON (Secretary of State for Scotland), in moving the vote, reviewed the work of the department during the past year, and there was a general debate on a variety of subjects of medical importance. A report of the debate will be published in THE LANCET next week.

HOUSE OF LORDS.

WEDNESDAY, JULY 9TH.

Assessment of Playing Fields.

Lord O'HAGAN asked His Majesty's Government—

Whether their attention has been drawn to the serious increases which have recently taken place in the assessmen of playing fields and recreation grounds for the use of villagers or attached to working-men's clubs, settlements, churches, and institutes; whether it is realised that the effect of the increased assessments will probably involve the giving up of many private playing fields because the present occupiers cannot pay the increased rates; and whether, in view of the importance of securing recreational facilities for developing the health and healthy enjoyment of the wage-earning classes in particular, it is intended to take any measures to relieve from the payment of rates and taxes bona fide non-profit-making playing fields for those who otherwise are unable to afford them.

The noble lord, who also moved for papers, said that under the reassessments which were taking place land was being assessed which had never been assessed before, and where the land was already subject to rates the assessments were in many cases being increased. Money was being raised in this way at the expense of health and recreation, and some of the sports clubs would have to double their subscription, which the membership could not afford, or cease to exist. These assessments were undoing a great deal of the work which had been done by the National Playing Fields Association, which had rendered splendid service.

The motion was supported by Lord DANESFORT, the Earl of DERBY (chairman of the committee of the National Playing Fields Association), and the Bishop of SOUTHWARK.

Lord MARLEY (Under Secretary for War), replying for the Government, said he was told that it was not at the desire of the National Playing Fields Association that this question was raised, in view of the fact that the Minister of Health was meeting that Association on the following day to discuss this subject with them in a very sympathetic manner. They must try to find a remedy for the effects of the Rating and Valuation Act, 1925, which attempted to stabilise and equalise the assessment of rates all over the country. The information obtained by the Central Valuation Committee appeared to show that in most of the counties and county boroughs concerned the proportionate increase in the assessments of playing fields had been less than the general proportionate increase in rateable value. He had no doubt that the Central Valuation Committee would be able to do much to meet the points that had been raised. Such information as the Government had did not suggest that any financial difficulties would follow the new assessments in the majority of cases. The Ministry had no evidence that any playing fields had been given up owing to the new assessments. A Bill to exempt playing fields from rating was defeated in Committee after having been opposed by the Association of Municipal Corporations, the County Councils' Association, and many other bodies. The Minister of Health was of opinion that the anomalies in the assessment of playing fields were in the same category as the assessment of other properties, such as hospitals and schools. The recommendations of the Central Valuation Committee would undoubtedly carry very great weight with the local authorities, and they would be published. It must be the unanimous wish of their Lordships to find a solution of these difficulties and to increase the number of playing fields, but they must not

consider that because one solution was put forward it was necessarily the right one.

Lord O'HAGAN, after expressing disappointment with the reply, withdrew his motion for papers.

HOUSE OF COMMONS.

WEDNESDAY, JULY 9TH.

Miners and Nystagmus.

Mr. TINKER asked the Home Secretary if his attention had been drawn to the increasing number of nystagmus cases certified for light work on the surface; if he was aware that employers refused to find them suitable work but reduced compensation to small amounts and, in some cases, took it away altogether; and if he would consider amending the Workmen's Compensation Act so as to prevent compensation being reduced until suitable work was offered. —Mr. CLYNES replied: I am well aware of the hardship arising not only in nystagmus cases but also in the case of many other partially disabled workmen, who under present conditions are unable to obtain any suitable employment. An attempt to provide a solution has been made this session in a Bill which is now before the House. I am afraid that all I can do at present is to assure my hon. friend that I recognise the importance and urgency of the question, and will do anything that is possible to secure a satisfactory settlement.

Mr. DUNCAN GRAHAM asked the Home Secretary whether he was aware that the coalowners of Lanarkshire made it a condition of employment that every man employed by them to work underground should sign a form that he had never been in receipt of compensation for nystagmus; if the man stated on the form that he had been on compensation for that disability he was refused employment; if he denied having suffered from nystagmus for the purpose of getting employment and the disability recurred he was deprived of compensation; and whether, as this was in effect an evasion of the Workmen's Compensation Act, he would take action to make the signing of such a form illegal.—Mr. CLYNES replied: I understand that the practice in the Lanarkshire coalfield is generally as described in the question. It would, I think, be unfortunate if all the men who had at any time suffered in any degree from miner's nystagmus should be debarred thereafter from any underground employment, and I propose to consult with my hon. friend the Secretary for Mines as to the possibility of arriving at some special arrangement with the industry in regard to the application of the Act to such cases.

Welfare of the Blind.

Sir KINGSLEY WOOD asked the Minister of Health whether he proposed to take any action concerning the recommendations in the recent report of the advisory committee on the welfare of the blind.—Mr. GREENWOOD replied: I am not sure what particular recommendations the right hon. gentleman has in view. Most of the recommendations contained in this report do not call for any action on my part.

Report on Maternal Mortality.

Dr. PHILLIPS asked the Minister of Health when the report of the departmental committee inquiring into the causes of maternal mortality would be published.—Mr. GREENWOOD replied: It is hoped that an interim report from this committee will be published before the end of this month.

Specimens at Royal Veterinary College.

Mr. RICHARD RUSSELL asked the Minister of Agriculture if he was aware that some thousands of pathological specimens of great value, on account of their rarity, had been destroyed at the Royal Veterinary College, London; and whether he proposed to make any inquiry into this loss to veterinary education and research.—Dr. ADDISON replied: I am not aware that the position is as stated in the first part of the question. According to my information, certain specimens at the College were destroyed as they were no longer in good condition. I understand that the governors of the College have already considered this question, and I can scarcely intervene in the matter.

Nourishment for Necessitous Children.

Mr. DAY asked the President of the Board of Education the number of local authorities at present providing meals and other nourishment for necessitous children; and what arrangements had been made for securing coöperation between the education and poor-law authorities.—Sir CHARLES TREVELYAN replied: 135 local education authorities provided meals for school-children during the week ended June 21st. With regard to the second part of the question, arrangements are generally made for securing coöperation by means of mutual exchange of information.

Dental Examination and Loss of Wages.

Mr. BOWEN asked the Minister of Health whether, in view of the fact that provisions of the National Health Insurance (Dental Benefit) Regulations, 1930, made provision that, as from July 7th next, a condition for the receipt of dental benefit was that a member of an approved society must, if required by his society, submit himself for examination both before and after treatment, and in consideration of the loss of wages likely to be incurred by members of approved societies in connexion with such attendances, he would consider amending such proposed regulations so as to provide for payment of actual loss of wages incurred by applicants who attended for such examinations.—Mr. GREENWOOD replied: There is no necessity for an insured person to suffer any loss of wages by reason of attendance for examination by a regional dental officer, as arrangements can aways be made, if necessary, for his examination outside his working hours. In these circumstances I do not think that any amendment of the regulation referred to by my hon. friend is required.

TUESDAY, JULY 15TH.

Medical Attention for Families of Service Men.

Mr. HORE-BELISHA asked the Secretary of State for War what arrangements were in force for providing medical attention for the families of officers and men serving in the Army.—Mr. T. SHAW replied: The following is the information asked for: The families of officers and soldiers on the married quarters roll are afforded medical attendance as a privilege so far as facilities are available from a military source. At practically all military stations there is a military medical officer or employed civilian medical practitioner whose duties include medical attendance on officers' and soldiers' families. If unfit to attend the medical inspection room, families on the married quarters roll may be attended in their quarters provided they reside within a radius of one mile from a point fixed by the general officer commanding (usually the medical inspection room). At certain stations where the strength of the garrison is large in comparison with the civil population, there is a military families' hospital to which the families of soldiers on the married quarters roll may be admitted. At stations where there is no military families' hospital a member of the family of a soldier on the married quarters roll may, in special circumstances, be admitted to a civil hospital at the cost of army funds. Hospital accommodation is not provided for the families of officers, but the families of officers in the Salisbury Plain area, and at Ismailla, where the local conditions are exceptional, may be admitted to the local military families' hospital on payment of the usual hospital charges, provided accommodation is available. At Aldershot a wing has been added to the military families' hospital, at the cost of local charitable funds, for the accommodation of the families of officers in that command. The charges for admission to this wing are fixed by the local committee, and all additional expense in connexion with the wing is borne by the committee. Families of soldiers not on the married quarters roll may also have such facilities as are available, but they cannot be visited at their residences by a medical officer. They may, under the special authority of the general officer commanding, be admitted to a military hospital on payment of 1*s.* a day.

Street Accidents to Children in London.

Mr. DAY asked the Home Secretary the number of street accidents to children in London (Metropolitan Police District and City of London) for the 12 months ended to the last convenient date.—Mr. CLYNES replied: The figures for the 12 months to March 31st last are, killed 297, and injured 10,944.

Health of the Mercantile Marine.

Mr. THOMAS LEWIS asked the President of the Board of Trade what progress had been made by the joint committee set up 12 months ago to consider and advise on any questions affecting the health of the mercantile marine; and when a report on the subject was likely to be made.—Mr. W. GRAHAM replied: The inquiries into the mortality statistics of seamen and the hygiene of crew spaces are making satisfactory progress, but it must necessarily be some time before the committee can complete its consideration of these problems.

SUBSIDISED AND NON-SUDSIDISED HOUSES.—In reporting a reply of the Parliamentary Secretary to the Minister of Health to a question by Mr. Hore-Belisha last week (July 12th p. 112), a tabular statement was inserted in which, by obvious error, columns 2 and 3 were transposed.

OBITUARY

FRANK EDWARD TAYLOR, M.D., M.R.C.P.Lond., F.R.C.S.Eng.

Dr. Frank Taylor, who died suddenly on July 1st, aged 58, was born in Leeds, the son of an Iron-founder, and was educated at the Leeds Boys Modern School. Entering the Yorkshire College (Victoria University), Leeds, he graduated first in arts and then in medicine. After experience as house surgeon at the Leeds General Infirmary he decided to specialise in obstetrics and gynæcology, and took up resident appointments at the Hospital for Women and Children, Leeds, and the Chelsea Women's and Queen Charlotte's Hospitals, London, besides working in Berlin during 1899. The Boer War interrupted his studies and in 1900 he joined the South African Field Force as civil surgeon, receiving the medal and three clasps for his services.

On his return Dr. Taylor pursued further studies in his chosen subject and added to the number of his qualifications by taking the F.R.C.S. Eng. in 1903, the M.R.C.P. Lond., in 1905, and the M.D. Lond. and D.P.H. Camb., in 1906; all his life he had a flair for passing examinations and for coaching others to do so. Appointments as gynæcologist on the staff of the North-West London and Hampstead General Hospital, the St. Marylebone General Dispensary, and the Eastern Dispensary now followed, and he seemed well embarked on the career he had chosen when he was compelled by ill-health in 1912 to relinquish his gynæcological work. He had been appointed in 1906 part-time demonstrator and then lecturer in the bacteriological department at King's College, London, and devoted the remainder of his life to bacteriology and pathology. During the war he was pathologist to the Lewisham War Hospital and for some years pathologist to the Royal Westminster Ophthalmic Hospital in addition to his King's College appointment.

Dr. Taylor won the admiration of his friends by his fight against ill-health and the disabilities ensuing therefrom. He had considerable literary ability and originality of ideas and published a number of useful communications. In the earlier part of his career these were mainly gynæcological, but later they ranged over widely separate subjects. With Prof. Dixon and Dr. Rosenheim he investigated the action of placental extract and he published papers on the Arneth blood count, vaccines, the absorption test, besides other work in collaboration with Sir Aldo Castellani, Capt. McKinstry, and Dr. Pickering. For many years he was an examiner on the Central Midwives Board and for the last 18 months was in charge of the vaccine laboratory of the Royal Herbert Hospital. He leaves a widow but no family.

GAVIN BROWN CLARK, M.D.Brux., F.R.C.S.Edin.

Dr. Gavin Clark, who died at Hampstead on July 5th, at the age of 83, was better known as a politician than as a medical man. After practising for a few years in London he was, in 1885, elected M.P. for Caithness, and identified himself with the Radical wing of the Liberal Party. The interests of his native Scotland had appealed strongly to him, and he played an active part in the passing of the Crofters' Act which had for its objects the relief of distress in the Highlands. Home Rule for Ireland also found in him a staunch supporter, and he was throughout his life a vigorous worker in the cause of international peace. Dr. Clark was for ten years Consul-General to the South African Republics and during the Boer war he was bitterly attacked for his opposition to that conflict—an attitude which cost him his seat in 1900. During the late war he was an active member of the Wounded Allies' Relief Committee, which had established hospitals in France and Serbia, and for his services he received the Belgian Order of the Crown and the Serbian Order of St. Sava. Dr. Clark was a keen socialist, a great traveller, and a man of wide sympathies. Mr. Ramsay MacDonald writes of him: "He has had a long and very useful life, and his name will always be associated with two great causes which he served with singular devotion—the Highlands and Peace." He leaves a widow with one son and a daughter, Mrs. W. A. Brend. A younger son, Captain W. B. Clark, R.A.M.C., was killed in the war.

MEDICAL NEWS

University of Dublin.

At recent examinations the following candidates were successful:—

M.D.

C. de L. Shortt and J. E. Wells.

M.CH.

N. L. W. Woodroffe.

FINAL EXAMINATION FOR M.B., B.CH., AND B.A.O.

Part I. Therapeutics, Hygiene, Pathology, &c.—L. L. Nel, J. L. du Preez, T. F. O'Donnell, Alfred Pollitt, Sydney Brass, A. L. Pennefather, E. W. West, P. P. Murphy, C. de V. Shortt, I. G. M'Intyre, Lambertus Lambinon, P. H. Stone, M. A. Shapiro, and Robert M'Neilly.

Part II. Medicine.—*S. H. Moore, N. A. Kinnear, A. H. Thompson, J. T. Robinson, T. A. Bouchier-Hayes, W. A. Robinson, E. S. Duthie, J. M. Gibbon, Reginald Bowesman, J. B. Scott, E. S. Tweedy, H. W. Dalton, R. D. Scott, Ruth R. Armstrong, J. E. R. Keyms, and A. A. Lisney.

Surgery.—*S. H. Moore, J. T. Robinson, J. M. Gibbon, A. H. Thompson, J. A. Dowds, T. H. Dockrell, T. A. Bouchier-Hayes, W. I. Chapman, N. S. Klass, A. H. O'Malley, P. L. O'Neill, Aaron Rakoff, R. P. M'Garrigle, and D. G. M'Caully.

Midwifery.—*P. C. Cosgrove, G. F. Ennis, Charles Bowesman, A. D. Egan, Alice V. Cunningham, A. J. O'Connor, H. St. G. Smith, D. G. Kennedy, and P. H. Peacock.

* Passed on high marks.

D.P.H.

Part I.—J. H. Bowyer, and P. J. Maguire.

Part II.—J. H. Bowyer, P. J. Maguire, W. H. Sexton, D. H. F. Milmo, and May F. M'Carthy.

University of Durham.

On June 26th and 27th the following degrees, diplomas, and licence were conferred:—

M.D.—E. C. Abraham, P. C. Arnold, Joshua Carse, J. A. Charles, Anne Fairweather, David Gamsu, H. V. Leigh, G. N. Myers, H. P. Nelson, S. D. Rowlands, J. M. Tait, Sydney Thompson, James Whillis, and (for practitioners of 15 years' standing) A. O. Gray.

M.B. and B.S.—H. H. D. Anderson, B. N. Bhandari, R. H. Clayton, Edna T. Everdell, P. N. Grinling, Lily Haugh, William Hunter, J. G. Lawson, Robert Manners, Thelma Mouat, Samuel Olswang, H. J. Peters, W. G. A. Swan, and J. E. Wilson.

B.Hyg. and D.P.H.—T. H. Blench, Jessie S. Dunlop, Annie M. C. Forster, R. G. A. McLaren, and E. T. Riordan.

L.D.S.—T. A. Ireland.

At recent examinations the following candidates were successful:—

THIRD EXAMINATION FOR M.B. AND B.S.

Pathology, Pharmacology, Public Health, &c.—W. C. D. Bewick, Eileen G. Marshall, J. A. Miller, A. H. Penman, and Edward Smith.

University of London.

At recent examinations the following candidates were successful:—

DIPLOMA IN BACTERIOLOGY.

Y. B. Abdoosh, H. R. Aggarwal, C. G. Anderson, J. G. C. Campbell, James Carmichael, F. P. Coyne, S. R. Pandit, and R. S. Twigg.

Royal College of Surgeons of England.

A quarterly meeting of the Council was held on July 11th, with Lord Moynihan, the President, in the chair.

The President announced the re-election to the Council of Mr. R. P. Rowlands, Sir Percy Sargent, and Mr. Victor Bonney. The newly elected members were introduced and took their seats in the Council. Lord Moynihan was re-elected President, and Mr. C. H. Fagge and Mr. R. P. Rowlands were elected vice-presidents for the ensuing year. Mr. R. H. Burne, F.R.S. (physiological curator), Sir Frank Colyer (honorary curator of the odontological collection), and Mr. C. J. S. Thompson (honorary curator of the historical section of the museum) were re-elected to their respective posts.

Mr. W. R. Le Fanu, the assistant librarian, was appointed librarian to the College from Oct. 1st next. Mr. E. G. Muir, M.R.C.S., was appointed Bernhard Baron research scholar. The Hallett prize for anatomy and physiology was awarded to George Qvist, of University College Hospital. It was announced that the Sir Gilbert Blane gold medal had been awarded to Surgeon Lieut.-Commander J. F. H. Gaussen, R.N.

D. S. M. Barlow, of Middlesex and University College Hospitals, was admitted a Fellow of the College, and diplomas of Membership were granted to R. D. Harding (King's College Hospital) and Violet R. Sharp (Royal Free), who had passed the necessary examinations and complied with the regulations.

Licences in dental surgery were granted to the following:—

A. H. Adcock, A. A. W. Beach, A. S. Bradshaw, S. H. Brown, J. J. Cochrane, G. R. G. Druce, F. A. Dyer, W. D. P. Evans, William Forsyth, Millice A. Freeman, A. H. Fuller, Julius Gottlieb, W. F. G. Harvey, Bernard Herson, L. B. Hilton, S. C. Holms, E. C. Humphreys, J. W. Jessen, H. S. Johnson, H. A. W. Lincoln, W. R. R. Mewton, G. E. Pedley, K. E. Pringle, G. B. Schofield, C. R. K. Smith, S. R. Smith, J. J. Stack, Louis Symonds, K. V. M. Taylor-Milton, C. G. Wadsworth, L. G. White, D. S. Wilson, and T. D. Wren.

Diplomas in psychological medicine were granted jointly with the Royal College of Physicians to 10 candidates, and diplomas in laryngology and otology to 17 candidates.

The Council elected the following professors and lecturers for the ensuing year:—

Hunterian Professors: Sir Arthur Keith (six lectures), Mr. Victor Bonney, Mr. Basil Hume, Mr. J. Paterson Ross, Mr. D. H. Patey, and Mr. J. W. Tudor Thomas.

Arris and Gale Lecturers: Mr. T. P. Dunhill, Dr. Donald Hunter, and Prof. H. H. Woollard.

Erasmus Wilson Lecturers: Mr. C. E. Shattock, Mr. C. P. G Wakeley, Mr. D. H. Patey, and Mr. R. T. Payne.

Arnott Demonstrator: Sir Arthur Keith.

Vacant Erasmus Wilson demonstratorships are to be advertised.

The President reported that Dr. Harvey Cushing, of Boston, U.S.A., had delivered the Lister memorial lecture on July 9th, and had unveiled a tablet in memory of the late Sir Anthony Bowlby, presented by some American surgeons who had been associated with him during the late war. Mr. L. Bathe Rawling, on behalf of the medical staff of St. Bartholomew's Hospital, presented to the College a copy of Sir William Llewellyn's portrait of the late Sir Anthony Bowlby.

Sir D'Arcy Power, the honorary librarian, presented to the Council, on behalf of the editors, the two volumes of Plarr's "Lives of the Fellows." The Lives may be obtained from Messrs. John Wright and Sons, Ltd., of Bristol, price 3 guineas (leather) or 2 guineas (cloth) for the two volumes.

The Council appointed the following assessors and officers, nominated by the Canadian Medical Association, for the primary examination for the Fellowship to be held at Montreal from Sept. 2nd to 5th:—

Assessor for Anatomy: Prof. S. E. Whitnall, McGill University.
Assessor for Physiology: Prof. John Tait, McGill University.
Superintendent of the Examination: Dr. J. C. Simpson.
Superintendent of Dissections: Prof. John Beattie.

A primary examination for the Fellowship is to be held in Australia in August or September, 1931.

Thursday, Nov. 13th, was fixed as the date of the Buckston Browne annual dinner of Fellows and Members.

Royal College of Surgeons of Edinburgh.

The following diplomas have been conferred:—

L.D.S.—I. B. MacQuarrie, R. K. N. Clarkson, W. B. Taylor, and M. N. Paterson.

University of Sheffield.

At recent examinations the following were successful:—

FINAL EXAMINATION FOR M.B., CH.B.

K. G. A. Barlow, M. B. Hallam, Firth Hudson, Constance N. Jenkinson, W. H. B. Moore, and Ethel H. Waddy.

Dr. John Rennie has been appointed Professor of Public Health, in place of the late Dr. F. E. Wynne. Dr. Rennie is Dr. Wynne's successor as medical officer of the city of Sheffield.

London School of Hygiene and Tropical Medicine.

In the recent terminal examinations of the Division of Tropical Medicine and Hygiene the following candidates were successful:—

Passed with Distinction.—A. B. Cook (Duncan medal), T. F. Anderson, W. K. Connell, D. R. McPherson, E. N. O'Neill, C. E. Roberts, R. G. Spink, D. E. Stewart, M. V. N. Sudds, and H. G. Timbres.

Passed.—C. A. Alvarado, E. Burton, G. Q. Chance, P. J. Cowin, B. P. Dutt, M. A. Gaffer, D. R. Griffith, L. R. Khan, A. H. H. El Kordi, E. M. Lourie, F. H. McCay, F. Marsh, E. C. W. Maxwell, D. Murray, T. H. Nolan, P. K. Rao, R. Shelley, H. M. Soar, T. W. Stephens, B. A. Taylor, W. F. O. Taylor, S. E. Theis, G. M. Tullidge, H. B. C. Wallace, E. M. Wijerama, W. H. Willis, E. D. B. Wolfe, and K. Wood-Martin.

University of Aberdeen.

On July 9th the following degrees were conferred:—

M.D.—**H. W. Mulligan, *J. R. W. Hay, *John Innes, *J. W. Lobban, Duncan Coutts (*in absentia*), R. P. Gammie.

Ch.M.—*Charles Donald.

** Honours for thesis.
* Commendation for thesis.

M.B. & Ch.B.—*J. W. Howie, *Ann L. Thomson, N. D. Allan, P. E. Attisha, A. R. Forrest, C. J. M. Geddes, C. A. Glass, Gordon Hutchison, I. D. Kitchin, A. D. Macdonald, G. D. McKenzie, John Morrice, J. M. Ritchie, C. W. Robertson, John Seed, L. G. Shearer, H. M. Sinclair, J. R. Slessor, Anne Smith, R. A. Stephen, M. L. Thomson, J. W. E. Webster, and W. D. Wilson.

D.P.H.—V. L. Ferguson.

* With second-class honours.

University of Liverpool.

Applications are invited for the Samuel Turner Fellowship of £600 a year for research on cancer, in the first instance by tissue culture. Particulars will be found in our advertisement columns.

Royal Institute of Public Health.

Lord Reading has accepted the Presidency of the congress of the institute to be held at Frankfurt in May, 1931.

Trinity College, Dublin.

Miss Sarah H. Purser has given a sum of money to bring in £100 per annum in order to found a lectureship as a memorial to her brother, the late Dr. John Mallet Purser, who held the Chair of the Institutes of Medicine in the School of Physic for 27 years, and was for eight years Regius Professor of Physic. Several years ago Dr. Purser made a gift of £10,000 for the advancement of medical and scientific teaching in the University, and the interest on this sum has been the means of providing additional apparatus for teaching.

Donations and Bequests.

The late Mr. George Frederic Grant, J.P., of Kingston-on-Hull, among other bequests, left £500 each to the Hull Royal Infirmary and the Victoria Hospital for Sick Children, Hull; £100 each to Hull, East Yorks, and Lincolnshire Institution for the Deaf and Dumb, the Hull Blind Institution, and the Hull Jubilee District Nursing Association.—By the will of Mr. Aba Mickler, of Newcastle-on-Tyne, a bed is to be endowed in the Royal Victoria Infirmary and the residence of the testator is to be used as a hospital for poor consumptives and poor persons suffering from diseases of the chest, to be known as "The Northern Counties Hospital for Diseases of the Chest" and incorporating the name of Aba Mickler. The Hospital for Diseases of the Skin, the Hospital for Diseases of the Throat and Ear, Newcastle-on-Tyne, the Hospital for Incurables, the Northern Counties Hospital for Diseases of the Chest, the Northern Counties Institution for the Deaf and Dumb are recommended in the will for consideration by the trustees.—By the will of Mr. John Charles Gray, of Barr Common, near Walsall, who left estate of the gross value of £34,425, with net personalty £33,589, the testator left £500 to the Walsall and District General Hospital. After other bequests the residue of the property will go to the British Red Cross Society, to be applied by them in and towards their British Empire Cancer Campaign Fund.

Opening of the Marie Curie Hospital.

The Marie Curie Hospital, 2, Fitzjohn's-avenue, N.W., whose construction and accommodation have been fully described in the pages of THE LANCET, was formally declared open on Thursday, July 10th, when Mr. Stanley Baldwin performed the ceremony in the presence of a large number of supporters and friends of the institution. Miss M. M. Chadburn, M.D., senior surgeon to the South London Hospital for Women, and chairman of the Cancer Research Committee of the London Association of the Medical Women's Federation, presided, and among others present on the platform were the French and Polish Ambassadors, the Lady Mayoress of London, Mrs. Baldwin, Prof. Winifred Cullis, Sir Cuthbert Wallace, Lady Briscoe, and Prof. E. H. Kettle. Miss Chadburn, in welcoming Mr. Baldwin, said that the Marie Curie Hospital was the institution organised in England by medical women for the radium treatment of women suffering from cancer and allied diseases, and was the first establishment of its kind. She briefly summarised the reasons why the hospital had come into existence, the main one being to carry on the treatment of cancer of the uterus in accordance with the lines adopted at leading clinics on the Continent. She gave the statistics relative to the incidence of cancer on the whole population and on women, where the prevalence of uterine cancer was stressed. The fact, she said, that the radium treatment gives hope of cure, in cases taken at an early stage, justified both their present activities as well as an appeal for more money to provide more beds. The hospital possessed 30 beds, and at least 50 were required, for "cancer patients cannot wait." They had been lent radium to the value of £12,000, and it was never idle.

Mr. Baldwin expressed his pleasure at identification with the movement, and declared that to politicians, who spent their lives in controversy, who lived in the dust of the world and worse, and daily saw the exposure of meanness and sordidness, an escape to an atmosphere of complete unselfishness was to bathe in a sweet and pure stream of English life. Those who worked in the treatment of disease by radium had no thought of wealth, and were prepared to sacrifice their health and even their lives in the attempt to harness the wonderful substance to the service of mankind, facing the eternal verities of life, death, and truth. The Marie Curie Hospital he regarded as a memorial to this work, and to that band of martyrs, the early radiologists. In the researches to be carried on there by women, it might be that the supreme honour would be earned of discovering the origin of cancer, but who made the final discovery did not matter, for all who toiled to that end shared the honour.

The French ambassador read a telegram of good wishes from Mme. Curie, and eulogised her scientific work when associated with her French husband; and the Polish ambassador described how Mlle. Sklodowska derived from her Warsaw teaching and upbringing a scientific background.

Mr. Baldwin then declared the hospital open.

A vote of thanks to Mr. Baldwin was proposed by the Lady Mayoress, who recalled the support given at a Mansion House meeting to the scheme for adding to the hospital. This vote was seconded by Prof. Winifred Cullis, who pointed out the similarity of Mr. Baldwin and Miss Chadburn in their studiously moderate manner of stating important things, when Mr. Baldwin replied that, "to employ meiosis," he felt not unhonoured.

The front door of the hospital was then unlocked by Mr. Baldwin with a key presented to him by Miss E. Scott, A.R.I.B.A., the architect.

Middlesex Hospital Medical School.

The opening ceremony of the winter session will take place at the Queen's Hall, Langham-place, on Oct. 1st at 3 P.M. Mr. Arthur Greenwood, Minister of Health, will distribute the prizes, and Mr. Eric Pearce Gould will give the introductory address. The annual dinner of past and present students will be held at the Savoy Hotel in the evening.

Appointments

BOYLE, A. B., M.B., B.Ch. Belf., has been appointed Medical Officer of the No. 2 Londonderry Dispensary.

BROWN, F. W. C., M.D. Aberd., Medical Officer of Health and Schools Medical Officer at Hyde.

Certifying Surgeons under the Factory and Workshop Acts: BOSCHI, E. J., L.R.C.P. Lond., M.R.C.S. (Bruton, Somerset), and WILSON, C. L. L., L.R.C.P. Lond., M.R.C.S. (Sittingbourne).

HEATH, W. E., M.B., B.S. Lond., D.O. Oxf., Hon. Ophthalmic Surgeon to St. Bartholomew's Hospital, Rochester, and to the Gravesend and North Kent Hospital, Gravesend.

WRIGHT, W. E. M., F.R.C.S. Edin., Medical Officer to the Boston (Lincolnshire) Poor Law Institution.

Medical Diary

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, July 21st to SATURDAY, July 26th.—INFANTS HOSPITAL, Vincent-square, S.W. Special Course in Diseases of Infants. Every afternoon from 2 P.M., Lectures and Demonstrations. Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, July 21st.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Throat, and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Ear, Nose, and Throat Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Children's Diseases Clinics. Operations.

WEST LONDON POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, July 21st.—10 A.M. to 1 P.M., Skin Department, Genito-urinary Operations, Surgical Ward Visit. 2 P.M. to 5 P.M., Operations, Surgical Ward Visit, Medical, Surgical, Eye, Gynæcological Out-patient Departments.

TUESDAY.—10 A.M. to 1 P.M., Medical Ward Demonstration, Surgical Clinical Demonstration. 2 P.M. to 5 P.M., Operations, Medical, Surgical, and Throat, Nose and Ear Out-patient Departments.

WEDNESDAY.—10 A.M. to 1 P.M., Medical and Surgical Ward Visits. Children's Medical Out-patient Department. 2 P.M. to 5 P.M., Gynæcological Operations, Medical, Surgical, and Eye Out-patient Departments.

THURSDAY.—10 A.M. to 1 P.M., Neurological Department. Demonstration in Treatment of Fractures. 2 P.M. to 5 P.M., Medical, Surgical, Eye, and Genito-urinary Out-patient Departments. Operations.

FRIDAY.—10 A.M. to 5 P.M., Medical Ward Visit. Skin and Dental Out-patient Departments, Medical Clinical Demonstration. 2 P.M. to 5 P.M., Medical, Surgical, and Throat, Nose and Ear Out-patient Departments. Operations.

SATURDAY.—10 A.M. to 1 P.M., Children's Medical, Bacterial Therapy, and Surgical Out-patient Departments, Medical Ward Visits, Throat, Nose and Ear Operations.

Births, Marriages, and Deaths

BIRTHS.

ALLEN.—On July 10th, at Hillbury-road, S.W., the wife of Dr. N. Howard Allen, Woolwich, of a son.

CARDELL.—On July 6th at Devonshire-street, W., the wife of J. D. Magor Cardell, F.R.C.S., Burgess Park-mansions, N.W., of a daughter.

MURPHY.—On July 7th, the wife of Dr. Denis Murphy, Earlsfield-road, Wandsworth Common, S.W., of a son.

MARRIAGES.

CHIESMAN—RENNIE.—On July 12th, at Holy Trinity, Brompton, Walter Eric Chiesman, M.A., M.B., M.R.C.P., to Féodora Rennie, younger daughter of the late Frank Rennie, M.D., of Sway, Hampshire, and Mrs. Rennie, Princes-gardens, S.W.

McILRAITH—WOODS.—On July 10th, at All Souls, Langham-place, W., Charles H. McIlraith, M.D., &c., Harley-street, and Half-Moon lane, S.E., to Eileen Valerie Woods, daughter of the late E. MacAlpine Woods, J.P., &c.

SEWARD—MURPHY.—On July 10th, at the Catholic Church, Okehampton, Charles Mackay Seward, M.D., M.R.C.P. Edin., to Anne, elder daughter of Mr. and Mrs. F. Murphy, of Exbourne, Devon.

SPOOR—PATTISON.—On July 7th, at Oxford, William H. Spoor, M.A. Camb., M.R.C.S., L.R.C.P., to Sybil de H. R. Pattison, M.R.C.S., L.R.C.P.

WHIMSTER—EDWARDS.—On July 5th, at St. Mary's Church, Crumpsall, William Swanson Whimster, M.D., M.R.C.P., of Glendarroch, Lenton Boulevard, Nottingham, to Madge Elizabeth Edwards, M.B., Ch.B., younger daughter of Mr. and Mrs. F. F. Edwards, of Crumpsall, Manchester.

DEATHS.

ASHWORTH.—At Worthing, on July 11th, James Henry Ashworth, M.D., late of Halstead, Essex, aged 82.

BELL.—On July 9th, at Polwarth-grove, Edinburgh, after a long illness, Colonel George James Hamilton Bell, C.I.E., I.M.S. (retired), aged 69.

BULL.—On July 11th, at a nursing home in London, after a short illness, Lt.-Col. George Henry Bull, M.D., late of the I.M.S., of Monte Carlo, and of the Badminton Club, aged 77.

PRIOR.—On July 8th, at Darlington, Miles Prior, M.B., B.S., Surgeon, late R.N. and ss. *Olympic*.

SMITH.—On July 13th, after a long illness, at Lyncroft, Otford, Kent, Lt.-Col. Sydney Browning Smith, C.M.G., I.M.S.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

REFLECTIONS ON THE TREATMENT OF PULMONARY TUBERCULOSIS

IN SWITZERLAND AND AT HOME.

By W. R. E. Harrison, M.R.C.S. Eng.,

LATE HOUSE PHYSICIAN, CITY OF LONDON HOSPITAL FOR DISEASES OF HEART AND LUNGS, VICTORIA PARK, E.

In my belief a tuberculous patient is more likely to recover if he remains in England than if he goes to the high Alps, and I think the time is ripe for reconsideration of a form of treatment which has become traditional. The observer who has time for only a short visit to the Alps may easily overlook factors which are important in determining which environment offers the best chance of successful treatment.

Switzerland as a Holiday Resort.

The reputation of Switzerland for winter sports is, of course, increasing. On all sides there are glowing accounts of the invigorating effect of its wonderful dry and sunny climate, and judging by the appearance of returning enthusiasts this praise is well deserved. The danger lies in assuming that what is good for the holiday-maker is also good for the consumptive.

There is too much loose talk about "plenty of fresh air and sunshine" as though these were the most important elements in the treatment of tubercle. Undoubtedly the fresh air idea when it was first introduced marked a big step forward, and the whole sanatorium régime has evolved from it. But further advance has been made since then and fresh air no longer holds the first place. In fact, it can be confidently stated that by itself fresh air is not of much use, and may even be indirectly harmful if the patient is led to believe that by living in fresh air he is doing all that is necessary.

As to sunshine, it is difficult to see why this should be recommended at all during the active stages of the disease, since we are well aware of its power for harm, while any good that it may do is not proven. The present craze for sunshine and sun bathing should make medical practitioners careful to warn their phthisical patients against its risks. If only the slogan "plenty of fresh air and sunlight" could be lived down and replaced by some such phrase as "rest, prescribed exercise, and a healthy environment," in that order of importance, the public would become more familiar with the therapeutic methods of the present day and the alleged advantages of Switzerland would receive more careful scrutiny.

It may be suggested that Alpine life stimulates metabolism and increases the number of red cells in the blood; or even that the dry air "dries up" the sputum or fluid from a pleural effusion; but these are not the real reasons responsible for faith in Switzerland. The truth is that we carry in our minds a picture of the high Alps based on the recollection of a pleasant holiday spent in that country, probably in January. Weather conditions in London or in any other big English town at that time of the year were probably bad, and contrasted unfavourably with the clear brilliant air of the mountains. The cold air invited strenuous exercise, and the combination of exciting exercise, sunshine, and novel scenery caused an increase of the appetite and a sense of well-being. Little wonder then that we are apt to be biased in favour of the Alpine towns as health resorts. But these agreeable assets, far from being available for tuberculous patients, actually entail certain disadvantages and hindrances to successful treatment.

Sanatorium Life in Mid-winter.

Let us consider the life of a patient in a Swiss sanatorium during the twelve mid-winter weeks—a period chosen because it is said to be the time when Switzerland enjoys the greatest advantage over England.

First, there are the physiological considerations already mentioned—viz., stimulation of metabolism and an increased red cell count. But these are not really very important. Although metabolism no doubt rises in holiday-makers, there is little reason to expect the same result in patients. It must be remembered that in winter 19 out of the 24 hours of each day must be spent strictly within doors, in rooms centrally heated and poorly ventilated. The reason for this is that the sun is only visible over the mountain tops for about five hours a day, and for the remaining 19 hours the cold is too severe to permit of sitting outside. Patients are not advised, for the same reason, to open their bedroom windows. In a way this is all to the good, since tuberculous toxins are themselves powerful stimulators of metabolism, and the patient may well be able to dispense with further stimulation.

As for the increase of red cells in the blood, I cannot see how this can have any therapeutic value. Is it not simply a compensatory measure to overcome the disadvantage which otherwise would result from the shortage of oxygen in the air? If compensation becomes complete the patient is no worse off than he was before coming up to an altitude of 5000 feet. If, on the other hand, the destructive toxins prove too much for the regenerating processes, complete compensation is not attained and the patient is compelled to live in a state of chronic anoxæmia.

Occupation and Outlook.

We now come to more important considerations.

One of the tests of a good sanatorium is its capacity to provide cheerful, health-giving interests suitable for its patients. This is vital, since the tone or morale of a sanatorium depends on it; and here is one of the reasons why Swiss sanatoriums are inferior to English. The defect is not peculiar to any particular Swiss sanatorium; it is inherent in them all and comes from their being situated in the Alpine towns which cater for holiday-makers. The interest and "life" of these towns is almost entirely bound up with winter sports and the pleasures associated with hotel life. Now if a patient is to get any benefit out of treatment he must be debarred from these interests and pleasures, since they are not at all suited to the requirements of treatment. It is no use for a patient to think that he can lead a sort of modified holiday-maker's life. Very few patients are fit enough even to watch the skating, ice hockey, and the like. The intense cold on the ice rinks is highly dangerous to a debilitated person.

And if these interests are to be excluded, what is there left to do instead? Unfortunately very little. The Alpine resorts provide none of those varied interests associated with country life and scenery and outdoor nature study which help to make England eminently suitable to a patient undergoing treatment, and which often lead to new habits of life well calculated to maintain permanent arrest of the disease. It is really very striking how barren the Alpine resorts are in interests of this sort. English visitors as a rule do not realise it, because they are occupied with other things. At first the snow is interesting by reason of its novelty, but let the reader imagine a patient on his balcony looking over exactly the same bit of scenery day after day. There is no change, always the same featureless snow covering everything. It is not long before the monotony becomes intolerable and the patient finds himself longing for the sight of some green grass or brown earth or a shower of rain. The snow has the

property of making the landscape appear quite flat, like a bad painting on canvas, and the jagged mountain peaks crowding all round contribute very largely to this sense of flatness. The reason for this is, I think, that the mountain peaks do not constitute a true horizon; they seem much too close. It is the horizon which is largely responsible for that exhilarating sense of space and openness in a fine landscape, and when the horizon is absent, the effect produced is that of unhappy constriction. This point is important, since many people are accustomed to derive satisfaction and benefit from the contemplation of a noble landscape, and for these people prolonged residence in an Alpine valley becomes exceedingly depressing.

In case these views seem at variance with the well-attested excellence of Swiss scenery, it may be mentioned that none of these defects is noticed in the great open valleys of the lower parts of Switzerland where a distant range of mountains makes a truly noble prospect; and to the climber who scales the peaks bounding the valleys there comes, of course, a different feeling. But a patient cannot climb and must remain anchored in his narrow valley.

Exercise.

In Switzerland the prescribed daily exercise for patients is limited to walking and it is very soon borne in on one how unsuitable a mountainous country is for such purposes. The country ramble is impossible, for there is no country to ramble in. The daily walk must consist of the same dreary tramp along a very ordinary road with the perpetual snow all round. Little wonder if the therapeutic value of the walk is largely lost.

As an alternative the patient may make for the town and seek relief by looking at the shops. This may sometimes be interesting, but repetition soon leads to surfeit. The towns are in fact as unsuitable for patients as is the country. The real and only interests of the towns are for the holiday-makers. If a patient has been in the habit of deriving pleasure from the sight of beauty and harmony in architecture he will be as much at a loss in these towns as one who loves the open country. As everyone knows, the large Swiss towns in the lower levels are places of which the inhabitants are justly proud. But the Alpine resort is not of this order. It consists of a cosmopolitan jumble of disharmonious buildings dominated on the one hand by large and ostentatious hotels and on the other hand by somewhat sinister-looking sanatoriums with serried rows of balconies and beds. The effect produced by a prolonged stay in such a place is very dismal, and one is impelled to the conclusion that winter life in the high Alps is not at all suited to the needs of a sick person.

Spring and Summer.

If the winter is unsatisfactory, what about the spring and summer?

Well, the snow begins to melt. This is a tremendous fact. To one who has lived amongst continued frost and snow for three months this phenomenon is miraculous. The slush and mud that follows is usually apologised for by the Swiss; but it need not be, for to many patients the sight and sound and feel of water and mud coming at last after three months of deadly frost is a real delight. For a short time there is a great quickening of interest all around, and it is a thrill worth experiencing to witness the break up of the frost.

Unfortunately the promise of good times to come does not materialise. An altitude of 5000 feet is too high in this latitude for a good summer, especially when there are peaks all round of 8000 feet or more permanently covered with snow. The cold from these mountain peaks condenses the moisture out of every wind that blows, so that the valleys soon become choked with damp swirling mists. More snow and sleet comes down and melts again and so the summer drags on. In June the weather may resemble an English February, and it is not unknown for snow, sleet, or rain to fall every day for many weeks on end.

With such prevailing conditions I cannot see any reason whatever for recommending the high Alps as suitable places for the treatment of tuberculosis during spring or summer. The alleged advantages of the clear Alpine winter are unmistakably absent, while all the real disadvantages associated with altitude remain. Yet during this period the sanatoriums keep fairly full. Many of the patients are old-standing cases too ill to be moved, but a number of new ones continue to arrive. It seems a pity that these new cases should be handicapped from the start by the inclemencies of an Alpine summer, but there seems to be no way out of the difficulty so long as patients are sent to Switzerland, for anything is better than a policy of hasty change and change about in the treatment of tubercle.

The English Alternative.

I will conclude these notes with a short plea for England and English sanatoriums for the treatment of English patients.

How comes it that we are for ever running down our own climate until we delude ourselves into believing that the things we say about it are true? The foreign press does not fail to make capital out of this peculiar habit. With modern facilities of transport everyone who possesses money but who has lost health wants to be running off each winter to Switzerland or the Riviera or Algeria. At those places they may find distraction, but they will not find any mysterious element in the climate which will automatically cause them to regain health.

There is so much adverse criticism of our winter climate that people are getting quite scared of it and are coming to believe that it is unhealthy. This unfortunate tendency should be firmly corrected, and it should be more generally known that the results of treatment of phthisis in our home sanatoriums during the winter are, if anything, better than those obtained in the summer.

There seems to be a danger that we are getting so urbanised or rather suburbanised that we are losing touch with the country and the healthy rhythm of the changing seasons. For the city worker, the winter is apt to be thought of in terms of pelting rain on asphalt or stone pavements, whereas for the countryman, the winter has its own special interests and occupies a harmonious position in the cycle of the year.

But whatever mode of life a person has been used to, if he develops phthisis there must come a big change in his life at any rate during the months of active treatment, and it is of great importance that he should be started from the very beginning on the correct lines for re-establishing his health. Suppose he is sent to Switzerland and gets an "arrest" (the disease sometimes has a way of healing without any treatment at all), he will assume that the Swiss climate has done the trick and always in the future he will dread the winter at home, and will hanker to spend it abroad.

There are many unfortunate people like this who, if they have money, go out winter after winter wasting their time in an Alpine health resort, and what is worse they never seem to regain a sense of stable health. Such people can never hope to settle down to a steady job at home. But if, on the other hand, a patient has the good fortune to be sent to a good English sanatorium in the heart of the country he will receive a liberal education. He will be taught where the real dangers to health lie, and how to avoid them. He will be astonished to find how pleasant, varied, and health-giving our winter is, and quite often he will learn to appreciate the subtle changes that each month of the year brings to the countryside. Thus he may eventually return to his former employment with many added interests in life.

Of course, even under the best conditions so far devised, there are still many in whom the disease will progress to a fatal termination. It is a reproach to medical men that so many of these unfortunates should be allowed to die in a foreign land.

ASTHMA.

FOR the brief period 1928–29, cut short by the death of the benefactor who provided the funds for the Fellowship, Dr. Una Ledingham acted as Research Fellow for the Asthma Research Council. She spent some months of her Fellowship studying the methods of treatment used at various continental spas, and an account of her impressions forms part of the report of progress just issued by the Council.[1] She went to Mont Dore, Bad Reichenhall, Vienna, Hamburg, Berlin, and Bad Ems. At Mont Dore each patient is advised to undergo daily treatment for three weeks, and to take the cure during three concurrent seasons. Treatment in the main consists in drinking, inhaling, and bathing in the waters, with nasal douches of natural water or gas, gargles, and all forms of hydrotherapy as adjuvants. Of these processes she describes only the inhalation, gaseous, nasal douche, and the half-bath; the nasal and pharyngeal douches and general hydrotherapy differing from those in use elsewhere only in the utilisation of the natural water. She could get no definite indication relating to the factor in the cure regarded as most potent for different types of asthma. It appeared that a certain number of cases were relieved, that the inhalation had a beneficial effect in some cases of bronchial and dry asthma, and that the nasal gas was well appreciated by those patients with added nasal disturbance. Among points unfavourable to the particular type of inhalation in use Dr. Ledingham put the danger of chill from leaving a warm saturated atmosphere for a cold drier one, and the general exhaustion resulting from the great heat. At Bad Reichenhall compressed air treatment in special pneumatic chambers seemed to give considerable help to some asthmatics, though the cure here is not considered to be as specific for asthma as that at Mont Dore. At Vienna inquiry was made as to the reliability and permanence of the results obtained by Dr. Ludwig Hofbauer. The principle of his method lies in educating the patient to concentrate on breathing out, by teaching him to hum during expiration, and to remain, as far as possible quiescent during inspiration. All information received tended to endorse Dr. Hofbauer's own opinion that this simple method gives very good results in many cases.

The Lerchenfeld institute at Hamburg was visited. It is equipped with an inhalatorium, an ultra-violet light department, a diathermy department, an X ray department, and a bathing and hydrotherapeutic department. A large gymnasium is fitted with all forms of apparatus for correcting deformity, amongst which is an elaborate chair for controlling respiratory movements and for reducing overdistension of the chest. Dr. Ledingham ascertained that the greatest reliance is placed on the compressed air chamber, combined with saline inhalation—with nasal sprays and inhalations where there are nasal complications. Diathermy, heliotherapy, hydrotherapy, and exercises are used in specified cases. At Berlin a system of chest exercises suitable for asthmatics was studied. The exercises are mainly expiratory, beginning and ending in every case with a long expiration. They aim to teach control of both phases of respiration, particularly expiration, and also to reduce overdistension of the lung. The method is designed to prevent the occurrence of emphysema in asthmatic subjects and is said to reduce the frequency and severity of the attacks. The treatment produced a favourable impression on Dr. Ledingham, and such cases as were available for examination and inquiry gave strong evidence in favour of the exercises. Bad Ems is recommended chiefly for chronic conditions of the nose and throat and to a lesser extent for bronchitis, including those cases of asthma with associated bronchitis. The natural water is used for drinking, inhaling, gargling, spraying, and bathing and there is no particular technique associated with the cure.

Dr. Ledingham's critical observations (pp. 17 to 19) on those methods in vogue at the continental spas which she had had the opportunity of testing will be of interest to practitioners. The report also contains brief summaries of the work done in asthma research clinics in London, Glasgow, Leeds, Birmingham, and Edinburgh between October, 1927, and May, 1930.

BRITISH SOCIAL HYGIENE COUNCIL.

ON July 15th this Council gave a dinner at the Café Royal to members of the Colonial Office Conference. Mr. L. S. Amery, M.P., proposing the toast of Health and Empire, said that when the Colonial Development Fund was instituted the intention was that a considerable part should be devoted to building up health services. The best way of using it for this purpose was under consideration by a special committee, and he believed that recommendations would shortly be published. Some three-quarters of the inhabitants of the Empire lived under more or less tropical conditions, and over large areas the health problem underlay all others. Most of their many diseases were preventable, and notable among these were the venereal diseases which the Council was combating. Sir Ronald Storrs, Governor of Cyprus, told of the activities which had been started in the island by the visit of members of the Council. A local council had been formed, with the Governor as president, and five clinics had been set up.

Mrs. Neville Rolfe, secretary-general of the Council, proposing the health of the Guests, urged that English women living in the tropics should become social workers to the best of their ability. Their influence could be enormous, and there was something to be said for arranging that all women proceeding to the tropics should go through a short course of suitable training. It was important not to destroy native habits and ideas without putting something in their place. Mr. Srinavasa Sastri and Lady Baddeley responded, and the latter described the increasing effect of hygienic teaching in Nigeria. Dr. Drummond Shiels, Under Secretary of State for the Colonies, proposed the health of the President, and spoke in warm terms of the work done by the Council and its executive officers. Sir Basil Blackett, in his reply, touched on the decreasing confidence of the British about their mission to the world. While deprecating conversion with the Bible in one hand and the sword in the other, he regretted the decline of the missionary spirit, and he felt that the message of hygiene was still useful and important for Eastern peoples.

THE FLUELESS BEDROOM.

BEFORE the Section of Hygiene in Industry of the Congress of the Royal Sanitary Institute, recently held at Margate, Sir Francis Goodenough, president of the Section, delivered a brief address which brought to the attention of his audience two points of public importance, each point having added force by introduction from the chairman of the Gas Light and Coke Company.

The first subject to which he paid special attention is an extremely familiar one to readers of THE LANCET—namely, the damage done to town-dwellers through the deprivation of sunshine by coal-smoke, resulting in the carrying on of work under grimy and depressing conditions, accompanied by the heavy burden of expense for cleaning. Although an energetic society exists for the purpose of arousing public opinion as to the relative merits of burning crude coal when gas, electricity, coke, or smokeless fuel can be obtained, the society has never been well supported by the public, its efforts being much cramped by a lack of pecuniary backing. Medical men will welcome, therefore, the words of Sir Francis because they will feel assured that propaganda of similar sort will reach a large public through the activities of his company.

The second point in Sir Francis Goodenough's

address will not be so familiar to our readers, but his words here indicated a distinct public danger and one which is reflected in courts where medical evidence is of first value. "In connexion with the problem of hygienic heating," he said, "I should like particularly to enlist the assistance of this Institute and the whole of its members on one specific point which is presenting a new danger to health. There is a growing tendency on the part of builders to erect houses with one or more rooms, intended to be used as bedrooms, entirely unprovided with any flue, not even one sufficient to carry off the products of combustion from a gas-fire. This is actually done in some cases by local authorities for the deliberate purpose of encouraging the use of electric heaters—which they suggest render flues unnecessary. In nine cases out of ten the cost of electric heating drives the tenant to buy an oil stove or a cheap flueless gas stove. Neither is satisfactory, often not even safe; while an electric heater if installed has no ventilating effect, and only creates 'fug' in a flueless room." Like Sir Francis, we hold strongly that no bedroom should be without a flue to provide it with some degree of ventilation. An air brick, as he pointed out, can easily be pasted over by an occupant who hates draught, and medical men will agree with him that the prevalence of the flueless bedroom should be resisted.

DILAUDID E.

Part III. of the Dangerous Drugs Act, 1920, has been extended to include di-hydro-morphinone, its salts and any preparation, admixture, extract, or other substance containing any proportion of it. These may not be imported into or exported from the United Kingdom and Northern Ireland without a licence; as regards internal control the Dangerous Drugs (Consolidation) Regulations, 1928, will apply to them. The trade name of di-hydro-morphinone is dilaudide; it is not manufactured in this country.

Vacancies

For further information refer to the advertisement columns.

Aberdeen County Council, P.H. Dept.—Asst. M.O.H. £600-£750.
Aberdeen Royal Infirmary.—McRobert Lecturer in Malignant Disease. £800.
Aberystwyth Infirmary and Cardiganshire General Hospital.—H.S. £200.
Altrincham General Hospital, Cheshire.—Sen. H.S., and Jun. H.S. At rate of £150 and £120 respectively.
Ancoats, Manchester, Crossley Hospital.—Half-time Res. M.O. At rate of £50.
Barnstaple, North Devon Infirmary.—Res. M.O. At rate of £150.
Bath, Royal United Hospital.—H.P. and Asst. H.S. Each at rate of £120.
Birmingham City, Public Health Dept., Tuber. Section.—Asst. M.O. £350.
Birmingham, Dudley-road Hospital.—Jun. Asst. M.O.'s. All at rate of £200.
Birmingham, Midland Hospital, Easy Row.—H.S. £150.
Birmingham, Queen's Hospital.—H.S. to Ear, Nose, and Throat Dept., Ophth. H.S., and Res. Anæsthetist. Also H.P. to the Birmingham Nerve Hospital. Each at rate of £70.
Birmingham University.—Walter Myers Travelling Studentship. £300.
Blackburn Royal Infirmary.—Res. H.P. £175.
Bristol Royal Infirmary.—H.P.'s, H.S.'s, &c. Each at rate of £60. Also Cas. H.S. and Dental H.S. Each at rate of £80.
Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75.
Cardiff, King Edward VII. Welsh National Memorial Association.—Three Half-time Asst. Tuber. Officers. Each £300.
Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. Asst. Anæsthetist.
Chesterfield and North Derbyshire Royal Hospital.—H.S.'s. At rate of £100–£175.
City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.
Coventry and Warwickshire Hospital.—Res. Asst. H.S. £125.
Colchester, Essex County Hosp.—Asst. H.S. and Registrar. £120.
Croydon County Borough, Public Assistance Dept.—Res. Asst. M.O. for Mayday-road Hospital. £300.
Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £150.
Doncaster Royal Infirmary.—Three H.S.'s and one H.S. All at rate of £200.
East Ham Memorial Hospital, Shrewsbury-road, E.—H.P. Also H.S. to Special Depts. and Cas. O. At rate of £150 and £120 respectively.
Evelina Hospital for Children, Southwark, S.E.—H.S. Also Cas. and Out-Patient O. Each at rate of £120.
Fulham Hospital, St. Dunstan's-road, Hammersmith, W.—Third Asst. M.O. £250.
Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Res. Surg. O. Also H.P. At rate of £175 and £135 respectively.
Grosvenor Hospital for Women, Vincent-square, S.W.—Res. M.O. At rate of £100.
Huddersfield Royal Infirmary.—H.S. At rate of £150.
Hull Royal Infirmary.—Asst. H.P. Also Cas. H.S. Each at rate of £130.
Ilford, King George Hospital.—Hon. Dermatologist. Also Res. M.O. £200.
Indian Medical Service.—Commissions.
Islington Dispensary, 303, Upper-street, N.—Asst. Res. M.O. £220.
Kingston-upon-Hull, City and County of.—Res. M.O. for City Hospital, Cottingham. £350.
Leamington Spa, Warneford General Hospital.—Res. H.P. £165.
Leeds City.—Asst. Clin. Tuber. O. £500.
Leeds Jewish Herzl-Moser Hospital.—Res. M.O. £100.
Leeds Public Dispensary.—Jun. Res. M.O. £150.
Leicestershire County Council.—Asst. M.O.H. £650.
Leicester Royal Infirmary.—Cas. H.S. At rate of £125.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liverpool Heart Hospital.—H.P. £52.
Liverpool, Hospital for Consumption and Diseases of the Chest, Mount Pleasant.—Asst. M.O. and Pathologist. £150.
Liverpool, Royal Children's Hospital.—Res. M.O. At rate of £120. Also Two Res. H.P.'s, and Two H.S.'s. Each at rate of £100.
Liverpool University.—Samuel Turner Research Fellow. £600.
London School of Hygiene and Tropical Medicine.—Research Studentships in Entomology and Protozoology. Each £250.
Manchester, Ancoats Hospital.—H.P. At rate of £100.
Manchester, City of, Withington Hospital and Institution, Nell-lane, West Didsbury.—Four Asst. M.O.'s. All at the rate of £275.
Manchester Northern Hospital for Women and Children, Park-place, Cheetham Hill-road.—Sen. H.S. £130. Also Hon. Asst. Surgeon for Children.
Manitoba University.—Professor and Asst. Professor of Anatomy. $5000 and $3500 respectively.
Margate and District New General Hospital.—Res. M.O. £125.
Middlesbrough, North Ormesby Hospital.—H.P. £120.
Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Asst. Cas. O. At rate of £100.
Miller General Hospital, Greenwich-road, S.E.—Cas. O. £150.
National Hospital, Queen-square, W.C.—H.P. £150.
Newark General Hospital.—Res. H.S. At rate of £175.
Newport, Mon., Royal Gwent Hospital.—Hon. Radiologist.
Northwood, Middlesex, Mount Vernon Hospital.—Jun. Res. H.S. At rate of £250.
Norwich, Norfolk and Norwich Hospital.—H.S. £120.
Nottingham General Hospital.—H.S. At rate of £150.
Nottingham and Midland Eye Infirmary.—Res. H.S. £200.
Oldham Royal Infirmary.—Two H.S.'s to Special Departments. Each at rate of £175.
Portsmouth Royal Hospital.—Cas. O. At rate of £100.
Preston and County of Lancaster Royal Infirmary.—H.S. £150.
Princess Louise Kensington Hospital for Children, N. Kensington. H.S. At rate of £75.
Reading, Battle Hospital.—Asst. Res. M.O. £300.
Reading, Royal Berkshire Hospital.—Cas. O. and Res. Anæsthetist. Each at rate of £150.
Redhill, Royal Earlswood Institution.—Jun. Asst. M.O. At rate of £250.
Rochdale Infirmary and Dispensary.—Jun. H.S. £175.
Royal Chest Hospital, City-road, E.C.—H.P. At rate of £100.
Royal Society, Burlington House, W.—Lawrence Research Studentship. £300.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. for Out-patient Department. £150.
St. Pancras South Hospital, Pancras-road, N.W.—Second Asst. M.O. £350.
St. Peter's (Whitechapel) Hospital, 74, Vallance-road, E.—Second Asst. M.O. £450.
St. Thomas's Hospital, S.E.—Surgeon. Also Surgical Registrar.
Sheffield City of, Winter-street Hospital.—Asst. Tuber. O. £350.
Sheffield, City Hospitals.—Infections Diseases Res. M.O. £350.
Sheffield, Jessop Hospital for Women.—Registrar and Obstetrical Tutor. £500. Also Asst. H.S. At rate of £100.
Sheffield Royal Hospital.—H.S. to Ear, Nose and Throat Dept. Also Res. Anæsthetist. Each at rate of £80.
Sheffield Royal Infirmary.—Temp. Asst. for Path. and Bact. Dept At rate of £200. Also Two H.S.'s. and Ophth. H.S. Each at rate of £80.
Shrewsbury, Salop County Council.—Asst. M.O. £600.
Sidcup, Queen's Hospital.—First Asst. M.O. £400.
Southend-on-Sea County Borough.—Asst. M.O.H. £600.
Swanley (Kent) Hospital Convalescent Home, Parkwood.—Res. M.O. At rate of £200.
Swansea General and Eye Hospital.—Asst. Pathologist. £400–£500.
Swindon and North Wilts Victoria Hospital.—Res. M.O. £125
Truro, Royal Cornwall Infirmary.—H.S. £170.
Ventnor, Isle of Wight, Royal National Hospital for Consumption and Diseases of the Chest.—Asst. Res. M.O. At rate of £300.
Warrington Infirmary and Dispensary.—Res. H.P. ££75.
West African Medical Staff.—M.O.'s. Each £660.
West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Jun. H.P. At rate of £100
Western Hospital, Seagrave-road, Fulham, S.W.—Sen. Asst. M.O. £650.
Willesden General Hospital, N.W.—Jun. H.S. £175. Res. H.S. and H.P. £110 and £100 respectively. Also Registrars.
Wolverhampton Royal Hospital.—Cas. O., and Res. Anæsthetist. At rate of £125.
Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.
York County Hospital.—Res. Anæsthetist and Asst. H.S. £150.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Tighnabruaich (Argyllshire).

ADDRESSES AND ORIGINAL ARTICLES

NEUROHYPOPHYSIAL MECHANISMS FROM A CLINICAL STANDPOINT.

BY HARVEY CUSHING, M.D., C.B., F.R.C.S. (HON.),
PROFESSOR OF SURGERY, HARVARD UNIVERSITY.

Localisation of Function in the Interbrain.

PART II.*

IT can be gathered from what has gone before that indications of posterior lobe participation in our several hypophysial tumour-syndromes are, to say the least, inconspicuous, and what slight evidence of such participation there may be has been lost sight of owing to the recent diversion of our attention to the adjacent walls of the third ventricle. To this region we may now return, for there are other symptoms than the polyuria and adiposity already briefly considered, such as sugar metabolism, the thermo-regulatory mechanism, and the phenomenon of sleep, with which in the past the pituitary body had supposedly had something to do, and which it may yet prove to have.

When one speaks of localisation of function in a given part of the brain, it means nothing more than that the nerve centres, which are the primary receiving or discharging stations for impulses from or to other structures, are more or less clustered, and it was with the localised accumulations of cells in the cerebral cortex that experimental neuro-physiologists largely concerned themselves from the time of Fritsch and Hitzig and of Ferrier, until with Sherrington's decerebration experiments the study of the deeper and older parts of the brain really began.

What happened, for example, when the precentral gyrus was stimulated, when the calcarine cortex was damaged, when the vestibular nuclei were injured, was easily observed and comparatively easy to understand, but when glycosuria was produced by a puncture of the fourth ventricle, rigidity by decerebration or, as now, polyuria or adiposity by an injury of the hypothalamic tracts or centres, something far more fundamental and complex has occurred. In all instances, however, it may be taken as a principle that some governing function of a given part of the brain on tissues or organs that lie outside of it has been affected, whether by irritation or paralysis.

Now in the case of the diencephalon, we are dealing with an ancient portion of the brain which remains essentially unaltered in all creatures that have a brain at all. More than that, it proves to have direct neural connexions with the first of the organs of internal secretion to become recognisably differentiated and on which, as we have seen, the very perpetuation of the species depends. That structures in such close anatomical juxtaposition should be functionally independent would seem most improbable, even though we disregard their remote ancestry and demonstrable relationship.

DIABETES INSIPIDUS.

Something has already been said of the presumed mechanism of the hypophysial polyurias in the brief discussion of the antidiuretic properties of posterior lobe extract. Now that the position of the major hypothalamic nuclei are coming to be better understood both in experimental animals and man through such orderly studies as those of Malone (1910–1914) and of Rioch (1930), we may expect that someone soon will definitely determine the locus of the nuclear degenerations in those simpler cases of diabetes insipidus that are unaccompanied by tumours and which are supposedly post-encephalitic in origin. Though studies have already been made in this direction[1] and evidence favours the nucleus supraopticus, we do not yet know with certainty which of the two more important hypothalamic cell masses, this or the nucleus paraventricularis, is involved in the disorder, nor do the reports of experimental polyuria produced by hypothalamic punctures in the dog give us satisfactory histological information on this score. Certainly in none of these experiments could either of the bilaterally placed nuclei have been completely destroyed, and the tuberal nuclei, so far as can be determined, do not represent the source of the main fibre tracts that pass down the stalk to the posterior lobe.

Reports have been made by Levy [2] (1924) of retrograde alterations in the cells of the tuberal nuclei, and by Kary [3] (1924) of changes in the nucleus supraopticus after experimental injury of the canine posterior lobe, but what will prove more illuminating than the identification of such nuclear changes doubtless lies ahead of us in the pursuit of the secondary tract degenerations. The studies by Dr. Maddock of the tissues from his dog with experimental diabetes insipidus, which show an absence of nerve-fibres distal to the point of application of the clip, are, so far as I know, the first in which these secondary degenerations have been investigated.

What is known as the chiasmal syndrome leads surgeons nowadays to the frequent exposure of this region; and as will be subsequently pointed out, neurosurgical evidence strongly favours the nucleus supraopticus as the controlling centre for water metabolism. All this is in correspondence with the view that an experimental injury of the diencephalic part of the mechanism in question gives the most pronounced and enduring reaction. But there is no gainsaying that posterior lobe extirpations in the absence of tuberal injury will also produce the same diuretic response albeit a less striking one; and this P. E. Smith tells me he has observed in his hypophysectomies on the rat. Unfortunately no operation is likely to be devised which will serve to remove the epithelial investment of posterior lobe and tuber and leave the nervous structures intact, but it would probably lead to an intractable polyuria with the same certainty as an injury of the hypothalamic nuclei. It has been shown in Trendelenburg's laboratory (1928) that after extirpation of the posterior lobe the pars tuberalis and tuber cinerum contain an abundance of the antidiuretic and oxytocic substances normally to be found there only in trifling amounts, and that only when the tuber is subsequently destroyed does a persistent polyuria occur.[4]

* Part I. appeared in our last week's issue.

[1] Cf. Eaves, E. C., and Croll, M. M.: The Pituitary and Hypothalamic Region in Chronic Epidemic Encephalitis, Brain, 1930, liii., 56. These authors state that severely damaging nuclear lesions are less likely to cause diabetes and obesity than those less severe.

[2] Levy, F. H.: Zentralbl. f. d. ges. Neurol. u. Psych., 1924, xxxvii., 398.

[3] Kary, C.: Virchows Arch. f. path. Anat., 1924, cclii., 734.

[4] It is regrettable that the symptomatic effects of the canine hypophysectomies by improved methods, as reported by Dandy and Reichert (Bull. Johns Hopkins Hosp., 1925, xxxvii., 1) were not given in greater detail, particularly since the "stump of the infundibulum and the region immediately contiguous" was cauterised in a considerable percentage of cases to ensure destruction of all epithelial elements. Of 13 adult animals so treated, seven showed post-operative glycosuria and only five polyuria, whereas adiposity is not mentioned.

So far, then, as diabetes insipidus is concerned, the evidence at hand seems reasonably convincing that the disorder can be produced by nuclear degeneration from disease, by surgical injuries of the supraoptic region in operations about the chiasm, by the interruption of the nerve tracts in course whether from tuberal tumours, or punctures, by the experimental placement of a compressing clip on the infundibulum, and probably also (could this be accomplished) by complete removal of the epithelial investment which apparently elaborates the posterior lobe secretion—all of which indicates a diencephalo-hypophysial mechanism which can be broken at any one of three principal points—nucleus, fibre tract, and pars intermedia et tuberalis. We nevertheless, in regard to this most carefully studied of all diencephalo-hypophysial reactions, are left in doubt as to whether the phenomenon is stimulatory or paralytic, and the key to the problem may possibly lie in the neglect of the physiologist's contention that posterior lobe extracts have diuretic as well as antidiuretic effects, the former conceivably being the property of the epithelial investment, pars tuberalis in particular.

THE QUESTION OF ADIPOSITY.

An exaggeration of the elemental sensation of thirst is doubtless antecedent to these pathological polyurias just considered, and the imperative and irresistible call to quench it most certainly lies in this primitive region of the brain common to all animals. A no less primitive and equally impelling sensation is that of hunger, of which less has been said and written in connexion with the neuropituitary mechanisms. Patients with hypopituitarism, though they often become adipose, are notably small eaters, while acromegalics, on the contrary, often have a ravenous appetite scarcely appeased by five generous meals a day. This also was observed by Putnam, Teel, and Benedict in their dogs with experimentally induced overgrowth. In both states the sensation probably has something to do with the level of metabolism which is consistently low in hypopituitary, high in hyperpituitary states, but whence it originates (unless in the interbrain) is less clear.

Polyuria and its antecedent polydipsia are striking symptoms, often so abrupt in onset they can hardly escape notice. The acquirement of obesity, on the other hand, is an insidious process less likely to be observed and of which hunger is not a measure in the sense that thirst is of diabetes insipidus. It consequently presents an even more difficult problem than does that relating to the water balance, though there is little question but that the two will be found to have a similar explanation.

In all that has been written about fat metabolism in relation to the hypophysis and hypothalamus, emphasis has been laid almost exclusively on adiposity and little said of emaciation. If the adiposity is a paralytic phenomenon, as some assume polyuria to be, should we not expect to see a significant loss of weight as an irritative phenomenon? The condition of adiposo-genital dystrophy has so long engaged the attention of clinicians, the fact that there are lean as well as fat types of dyspituitarism associated with hypophysial as well as with hypothalamic tumours has not received the attention it deserves.

The tendency to adiposity, which first came to be recognised (1909) in hypophysectomised dogs and which we attributed to their increased tolerance for carbohydrates, has since been ascribed, as already stated, to accidental lesions of the diencephalon produced in the course of these early and awkwardly made operations. That such injuries frequently occurred there can be no doubt, and now that Smith has shown what extreme degrees of obesity may be produced by tuberal injuries in the rat without the possibility of injury to the gland itself, the question would seem to be decided. However, in one of Dr. Maddock's tuberal clip-experiments on dogs, after only a transient polyuria, the animal in the course of the succeeding months has become extremely adipose. So it seems to me not inconceivable that interference with the function of pars nervosa et tuberalis by blockage with retention of secretion through cicatricial formation may have had some part in causing the adiposity observed in our early experimental animals.

There remains, therefore, something to be said for the participation of the hypophysis in the mechanism of fat metabolism, and Smith himself admits that extirpation of the rat's gland in the absence of tuberal injury leads in time to a certain degree of adiposity even though it is less striking and prompt in appearance than after tuberal injuries. He nevertheless observed in his early attempts to destroy the rat's hypophysis by the intrasellar injection of a solution of chromic acid that in addition to the usual sequels of experimental ablation of the gland a marked adiposity occurred (and one may assume polyuria also though no mention is made of this) which may conceivably be accounted for by the diffusion of the corrosive along the stalk with destruction of the pars tuberalis without actual damage to hypothalamus. And in this connexion may be recalled the early observations on hypophysectomised tadpoles, a large and persistent fat organ being one of the four striking changes characterising the "pituitaryless" state. In contrast to its disappearance in the normal tadpole, this fat organ persisted in the experimental animals even on starvation, but injections of posterior lobe extract would cause its early absorption. This suggests that a similar treatment might have counteracted the adiposity of Smith's chromic-acid rats.

Though precise figures are not available, it has always been my impression that laboratory animals lost weight when given protracted treatment with posterior lobe extract; the substance may, therefore, be anti-adiposal as well as antidiuretic. It was shown by Coope and Chamberlain (1925) that the injection of pituitrin leads to an accumulation of fat in the liver in the course of eight to nine hours, and subsequent writers have found that the injections cause a disappearance or diminution of blood-fat, together with a decrease in the total fat of the peripheral tissues. Further and highly illuminating studies in this direction have been carried out in Biedl's clinic by William Raab (1926–28) who has found that minute doses of posterior lobe extract (pituitrin) when injected into the cerebral ventricles have a much more marked response in causing disappearance of neutral fat from the blood than when large doses are administered subcutaneously. The fat, meanwhile, is accumulated in the liver where it apparently is transformed. Since this pituitrin-effect is abolished by mechanical destruction of the tuber cinereum, by transection of the cervical cord or by section of the splanchnics as well as by drugs which supposedly paralyse the centres for heat regulation (aspirin, phenacetin, &c.), it was assumed that the extract stimulates the nervous centres of the tuber whence impulses pass, presumably by the descending hypothalamic bundles, to the cord and abdominal sympathetics and thence to the liver. Since it would appear that the normal operation of this neuroglandular apparatus is essential for the storage of such fat as is not immediately utilised by

he body, it is assumed by Raab that any disturbance ith the mechanism from hypophysis to liver will ead to an accumulation of fat, in other words, to besity.

Although in the clinic more marked examples of diposity are seen in patients with craniopharyniomas, which may well enough have damaged the iberal centres, than in patients with strictly itrasellar lesions that have not extruded themselves irough the diaphragma, an appreciable adiposity evertheless occurs in these cases also. So it is that ost patients with chromophobe adenomas in whom here is no possibility of tuberal injury (they at least irely if ever show polyuria) are definitely adipose. review of the clinical histories of our cases with is point in view reveals that in about 60 per cent. the females a sudden increase of weight (occasionally xtreme but averaging about 20 pounds) had occurred irly in the course of the malady more or less coincident ith the amenorrhœa and long before the evidences chiasmal pressure served to call attention to the nderlying hypophysial tumour. That the adiposity as not secondary to the amenorrhœa is shown y the fact that in approximately the same proporon of males a corresponding unaccountable early crease in weight had been recorded. The condition wholly comparable to the effect of an uncomplicated ypophysectomy on the weight of adult animals id it may, in all probability, be ascribed to the bliterative effects of the adenoma on the posterior be.

CARBOHYDRATE METABOLISM.

That the pituitary body was in some way related carbohydrate metabolism was first suggested the frequent association of acromegaly with abetes mellitus; and when it subsequently came known that both experimental and clinical ates of hypopituitarism showed a surprisingly gh tolerance for sugars,[5] this was looked upon another argument in favour of these states being e converse of acromegaly. Since that time, th the discovery of insulin and the development ready methods of estimating blood-sugar, an tensive reinvestigation by many interested persons the entire subject of carbohydrate metabolism has en made, and the pancreatic islets might well enough looked upon as having the entire matter of sugar sposal under their independent secretory control.

Nevertheless from the time (1858) of Bernard's gar piqûre to the present day, we have been nfronted by the certainty that some neurogenic chanism lies behind the normal utilisation of this m of food. Efforts have been made more precisely locate the so-called sugar centre in the fourth ntricle, and Brugsch, Dresel, and Levy have recently 921) provided evidence that it lies in the dorsal gus nucleus whence parasympathetic fibres are pposed to pass to the pancreas and sympathetic res to the adrenal. However this may be, and ubt has already been cast on their interpretation, e fourth ventricle can be little more than a relay tion for impulses producing glycogenolysis that me from higher up. In a long drawn out experintal study of the presumed rôle of the posterior pophysis in carbohydrate metabolism with Weed d Jacobson as my co-workers[6] we came to believe 913) that glycogenolysis was produced by the eration of a pituitary hormone set free by impulses aching the gland through the cervical autonomic system. These observations have never been repeated and our findings may be capable of other interpretations now that attention has been drawn to the importance of the hypothalamic region whence possibly our glycogenolytic responses originated rather than in the hypophysis itself. One thing, however, we did learn was that the experimental animal must be given the opportunity to store what we called available glycogen if the glycosuric response were to be obtained. Possibly on some such basis may lie the explanation of the fact that transient postoperative glycosurias are rarely observed on patients in the clinic after operations involving hypophysis or third ventricle, for they are usually conducted after at least a twelve-hour fast.

That the glycosurias which occur in approximately one out of every four patients with acromegaly are not an effect of the pituitary tumour in itself, regardless of its type, is further shown by the extreme rarity of glycosuria with pituitary tumours of other sorts; and though the admission must be made that two patients with chromophobe adenomas (out of a series of 200 or more surgically verified lesions of this type) have had coincidental diabetes, glycosuria in the other cases has never been observed even as a transient episode immediately following operation.

The diabetes mellitus of acromegaly, moreover, proves to be notably resistant to treatment by insulin, and it has been repeatedly shown that posterior lobe extract (pituitrin) will diminish or wholly counteract the blood-sugar-reducing effect of this product.[7] Since it is well known that posterior lobe extract produces, at least in animals, a transitory hyperglycæmia and glycosuria, it is a natural assumption that in acromegaly the neural portion of the gland is activated, possibly in connexion with the known tendency of these cases to have a high basal metabolic rate. What is more, the occasional spontaneous recovery from the diabetes mellitus of acromegaly with the continued progress of the underlying disease may point toward the gradual elimination of posterior lobe activity by pressure destruction from the enlarging tumour; and the occasional disappearance of an existent glycosuria after radical extirpation of a chromophilic adenoma suggests the possible resumption of activity in a previously compressed lobe.

With all this, and much of it is purely speculative, there is no gainsaying that the relation of the region in question to sugar diabetes is less evident than to that of water diabetes and to fat metabolism. Though temporary glycosuria may be provoked by experimental hypophysectomies or by hypothalamic injuries on animals, the effect is never prolonged, nor in my experience do operations for lesions of the hypophysis or third ventricle in man lead even to transient glycosuria.

A THERMO-REGULATORY CENTRE.

The existence of such a centre has long been postulated and such facts as we have in hand tend to place it in close relation to the primitive mechanisms under discussion. Indeed, Raab[8] (1926) marshals evidence in favour of its being identical with the mechanism which regulates the normal absorption and oxidation of fat within the liver which he takes

The Autonomic Control of the Pituitary Gland, Johns pkins Hosp. Bull., 1913, xxiv., 40.

[7] This insulin-inhibiting effect of posterior lobe extract has been shown by Burn (Quart. Jour. Pharmacol., 1929, i., 509) to lie in vasopressin and not in oxytocin. Houssay and Magenta find that hypophysectomised dogs go into convulsions after smaller doses of insulin than do normal animals.

[8] Raab, W.: Wämeregulation und Fettstoffwechsel., Zeit. f. d. ges. Exper. Med., 1926, liii., 317.

to be one of the essential factors in heat production. The necessity of a diet rich in fat to sustain warmth in arctic regions and the fat "gland" of hibernating animals on which the animal draws for sustenance during its winter period come immediately to mind.

An interference with thermo-regulatory control may lead to an abnormal fall or rise in body temperature. A well-known example of the former is the marked fall in body temperature after high transection of the spinal cord by wounds; another, the extreme elevation of temperature that occasionally follows intracranial operations. Both conditions are prone to be fatal and in both, in my experience, the victims are likely to feel comfortable and have no consciousness of the altered body temperature.

In the early experimental canine hypophysectomies, which often led to what was called cachexia hypophyseopriva, the gradual fall in temperature to the time of death in the course of five to ten days was often extreme, almost reaching that of the environment. Injections of fresh emulsified gland served as we thought to check the fall or even to re-elevate the temperature, but efforts to re-establish warmth by external applications of heat seemed merely to hasten death. It is a matter of general knowledge that patients with tumours that compress or destroy the posterior lobe, such as the common adenomas of chromophobe type, suffer from cold and have a consistently subnormal body temperature often averaging as low as 97° F. This might possibly have some connexion with their lowered metabolism; and the low body temperature and low metabolism of hibernating animals is proverbial.

Smith has called particular attention to the inability of his hypophysectomised rats to maintain a normal body temperature. One would naturally suppose that in these hypopituitary states a prompt rise in temperature would follow the injection of posterior lobe extract, but as a matter of fact it has, at least at the outset, just the opposite effect. Even if given intravenously, the extract causes, among other effects, a slight fall in temperature, but if injected into the ventricles the effect may be so pronounced as to be nothing short of startling. In one instance the rectal temperature fell to five degrees below normal and this was followed after three or four hours by a wave of pyrexia after which the patient experienced a marked sense of well-being. How to account for this unexpected antipyretic action of the drug is problematical.

Even more striking are the counterposed states of pyrexia. What is known as post-operative hyperthermia has long been a bête noir of neuro-surgeons. It is most likely to occur, particularly in children, after sudden, complete emptying of the ventricles and is one of the most dreaded consequences of radical extirpations of tumours which leave the floor of the dilated fourth ventricle widely exposed and which, at the same time, thoroughly empty the greatly distended and hydrocephalic cerebral ventricles. The body temperature may rise in the course of a few hours to 106° or even 108° F., the extremities meanwhile being so cold and clammy as to mislead the attendants and incline them to apply external heat.

Similar disturbances are known to follow operations for tumours of the third ventricle. I have recently removed a large suprasellar meningioma from a patient with a chiasmal syndrome, who, in the absence of any other post-operative symptoms referable to the third ventricle, for the subsequent ten days had a prolonged unremitting elevation of temperature, unassociated with leucocytosis or any evidence of infection. It was an unaccountable thermic wave almost like the temporary wave of polyuria th may follow one of these operations, slowly to retu to normal. Many other examples of this same ki might be given. The fact that these neurogen hyperthermias are notably influenced by antipyret drugs which are supposed to act directly on cerebr centres is also of significance.

On experimental grounds, a high and abru thermic reaction has been occasionally seen aft hypothalamic injuries of various kinds, and su studies as have been made in this direction by n associates have led some of them to believe that puncture in the region of the corpora mamillar is more likely than any other to produce the The whole subject, in short, is one which needs furth detailed study, and the recent perfection of apparatus which will permit of a continuous reco of body temperature will make further investigatio more precise than was formerly possible.

From what information we have, whether in cli or laboratory, it would appear that experimen or surgical lesions, whether in third or fourth ventric may lead to hyperthermia, and this suggests a pat way from the posterior diencephalon through t descending bundles to the cord, sympathetic nervo system, and viscera. In this connexion we m recall that Cannon's sympathectomised anim were no longer able to regulate their body temperatu but became hypothermic in a cold room and hyp thermic in heated ones, due presumably to the f that regulatory impulses from the hypothalam had been cut off.

PATHOLOGICAL SLEEP.

On what grounds the tortuous intracranial segme of the internal carotid arteries, whose branch enter the rete mirabile, came to be called "t sleepy arteries" is lost in antiquity, but for so reason or other the idea has prevailed that e function of sleep was ascribable to this regi There seemed to be something more in the idea th pure conjecture, but just what the mechanism f sleep and its alternate phase of waking might e was undetermined. Among theories innumerab that there may actually be a diencephalic cen for the process has been claimed, and the rec demonstration by Hess [9] (1929) of a definite hy thalamic area in the cat stimulation of which promptly induce a condition which is indistinguisha from sleep points suggestively in this direction.

Then, too, we have had before us, these past 15 ye the all too common examples of lethargy associat with encephalitis, a malady whose effects are pr to strike at this particular part of the brain as sho by other symptoms unmistakably hypothalamic origin. Accordingly, the not uncommon clinical sta of periodic somnolence called narcolepsy, which characterised, in the absence of any other sympto by periods of sudden irresistible drowsiness weakness, are commonly regarded as post-encep litic disturbances akin to parkinsonianism. And it is not without interest that patients, in whom th states of narcolepsy occur, oftentimes coincident become abnormally adipose. Pathological somnole is also prone to accompany such of the craniophar giomas as cause deformations of the third ventri but it is a still more common feature of what been called the hypersomnic form of brain tumour [10]

[9] Hess, W. R.: The Mechanism of Sleep, Amer. Jour. Phy 1929, xc., 386.

[10] A series of striking cases of this sort has been reported i the writer's clinic by J. F. Fulton and P. Bailey: Jour. N and Ment. Dis., 1929, lxix., 1, et seq., with complete bi graphy of the subject.

namely, the gliomatous lesions that arise from the walls of the third ventricle.

Thus it would appear that pathological sleep, and conversely of course abnormal wakefulness, in all probability are states induced by a disordered function of the hypothalamus, but we cannot at the same time lose sight of the fact that somnolence is also a characterising feature of many pituitary disorders in which the diencephalon can by no possibility have sustained direct damage. This is particularly true again of the chromophobe adenomas which are often associated with a notable drowsiness which 16 hours of sleep out of the 24 will sometimes scarcely satisfy; and the fact that polyuria is rarely seen in these cases would further emphasise the fact that the diencephalon has escaped injury.

There is another thing about sleep that deserved consideration—namely, its rhythmical periodicity. Cyclicism, which may be diurnal, lunar, or seasonal, is a peculiarity of many physiological processes. The unaccountable periodicity of œstrus and of menstruation, of rutting, and of hibernation are examples. That these cyclic occurrences are primitive and fundamental to the species there can be no question. The sloth awakens merely to take food and procreate. Hibernating or estivating creatures pass whole seasons unfavourable for sustenance with their metabolic processes so far slowed down they can survive meanwhile on their own tissues. That these processes are somehow under the control of this ancestral diencephalo-hypophysial apparatus seems most probable, for it at least accounts best for many of the physiological changes that are known to occur during sleep.

Some years ago (1915) the attempt was made in collaboration with Emil Goetsch[11] definitely to join hibernation on the pituitary body, but our opportunities for putting it to a conclusive test were inadequate. Unquestionably the secretory apparatus that controls tissue metabolism must be essentially inactive during hibernation just as it is relatively so in hypopituitary states, and since the hypophysis plays an even more definite governing rôle in these processes than we then ventured to believe, it would seem highly probable that winter sleep is made possible by the seasonal switching off of a diencephalo-pituitary mechanism which leads to sleep, oliguria, poikilothermia, slowed pulse and respiration, and the consumption of stored tissue fat at its lowest rate. And it may also be noted that on awakening from the hibernating state almost certainly from resumption of the activity of the anterior hypophysis and its influence on sex, the mating or rutting season usually sets in.

On the grounds of clinical experience, one must concede that after operations for hypophysial tumours, however radical they may be, post-operative hypersomnia is rarely seen. Only after operations in which the floor of the third ventricle has been subject to contusion, and only infrequently then, do we see evidence of pathological sleep of such prolonged nature as to excite comment. In a recent case after the removal of an unusually large olfactory groove meningioma which so far overlapped the chiasm and sella turcica as to cause marked deformity of the third ventricle, the patient during the course of the operation under local anæsthesia went into a profound, motionless sleep from which she did not gradually awake until nearly two weeks later. On the other hand, in the few cases in my experience in which tumours have been successfully removed from the cavity of the third ventricle, there has been no post-operative tendency either to abnormal drowsiness or wakefulness in spite of the inevitable contusion of the ventricular walls.

[11] Jour. Exper. Med., 1915, xxii., 25.

Diencephalo-sympathetic Mechanisms.

From what has preceded, the tendency to overload the third ventricle with functional responsibilities already begins to be apparent. What is more, there is an irresistible temptation anatomically to allocate these several functions in specific centres.[12] Whether this is wholly justifiable may be doubted, though we need not forget the rôle phrenology once played in adjusting us to the idea of localisation of function in the cerebral cortex. In addition to its highly important relation to the vegetative nervous system, the hypothalamus has come to be looked upon as a place where "emotional reactions are integrated." The uninhibited reactions of Goltz's famous partly decerebrated dog, which were known to all students of neurology 30 years ago, have been newly investigated by Cannon[13] and his pupils, who describe in decorticated animals an quasi-emotional (pseud-affective) state, designated "sham rage," the hypothalamic source of which Bard[14] subsequently succeeded in delimiting.[15] Since this state is accompanied by the same increase in blood-sugar, elevation of blood pressure, sweating, and outpouring of adrenalin, it is evident that the region lies in direct connexion with the spinal ganglia of the sympathetic nervous system. And recently Beattie and his co-workers[16] in their study of experimental cardiac arrythmias have furnished anatomical proof of this connexion by actually tracing the degenerations that follow experimental subthalamic injuries of the posterior part of the third ventricle. There is much more of this that might be told, but enough has been said to indicate what a promising field of experimentation has been opened up by these successive disclosures that serve closely to relate the diencephalon to metabolic processes, to the primary emotions, and, lastly, to the sympathetic nervous system.

With this mention of what may be regarded as a higher vasomotor centre in the posterior hypothalamus whence non-medullated fibres descend in the spinal cord to be distributed to the viscera, it would appear that we are now getting far removed from any possible participation of the hypophysis in this mechanism—yet we may not be so sure of this. It was shown by W. E. Dandy in my laboratory in Baltimore many years ago[17] that sympathetic fibres spreading from the carotid plexus could be stained by intravital methods and traced along the vessels of the stalk to the anterior hypophysis.[18] It was on this basis that the subsequent study, to which allusion has already been made, was undertaken with Weed and Jacobson, in the attempt to determine whether the autonomic fibres in question could be experimentally shown to have an effect on the pituitary body. We had observed that in dogs a puncture of the third ventricle

[18] Cowdry, E. V. (1930), has recently demonstrated in contact with the cells of this part of the gland the internal reticular apparatus of Golgi.

in the region of the hypophysis was almost as certain to produce glycosuria as a Bernard piqûre. Having then no reliable method of testing blood-sugar, we relied solely upon demonstrable glycosuria and soon found that in the same animal a succession of lesions (a fourth ventricle puncture, transection of the spinal cord at the fourth thoracic segment, stimulation of the superior cervical ganglion, and stimulation of the exposed hypophysis) could provoke an outpouring of sugar provided sufficient time was allowed between sessions for a reaccumulation of available glycogen.

These experiments doubtless are capable of reinterpretation in the light of new knowledge, but the point I wish here to emphasise in again mentioning them is that Bernard's piqûre may possibly cause glycosuria by injuring the descending hypothalamic bundles which lie superficially placed in the midline of the roof of the fourth ventricle. This, however, is not the only effect that lesions of this important tract may produce. Median cerebellar tumours that arise from the roof of the fourth ventricle are of common occurrence, and of late years, particularly since the advent of electro-surgical devices, they have come in large numbers to be radically attacked and removed. In this process the entire floor of the widely dilated ventricle is laid bare to view with the likelihood of its being subjected to trauma.

For reasons heretofore mentioned, a post-operative glycosuria is rarely observed after these surgical exposures of the fourth ventricle, though a post-operative hyperthermia, as already stated, is a not uncommon sequel. And while on this particular subject there is still another matter to which attention may properly be called. Three fatalities from acute perforations (one gastric and multiple, one duodenal and double, and a third œsophageal) have followed radical extirpations of cerebellar tumours, in two of them the fourth ventricle having been widely opened. The only possible explanation of these disconcerting accidents—and similar observations have been reported in medical literature—is that something injurious has happened to the nervous mechanism which in some way protects the gastric mucosa from auto-digestion. It is well known that most patients with peptic ulcer have an antecedent history of worry or apprehension associated with mental strain or fatigue, episodes of this kind being the usual preliminaries to recurrence of symptoms after their temporary recession; and I have been struck by the frequency with which patients with intracranial and particularly with third ventricle tumours have previously or subsequently had symptoms suggestive of gastric or duodenal ulcer.

All this concerning a diencephalo-sympathetic mechanism, which harks back to the early postulation by Kredel and Karplus of a cerebral representation for the sympathetic system, would appear to be remote from any conceivable bearing on the pituitary body. However, the fact emphasised by Raab, in his studies of fat metabolism that posterior lobe extract is particularly effective when injected into the ventricle, has led us to administer the extract in this way in a number of patients with pronounced hypopituitary states. They had all been previously operated upon for pituitary adenomas, and the injection was easily made through one of the burr openings for the craniotomy. We anticipated that there would be a rise in basal metabolic rate, in body temperature, and in blood pressure, possibly also a temporary hyperglycæmia; but quite the reverse happened.

The reaction has not been marked in all instances but when marked, almost immediately, and certainly before the extract could reach the blood stream, the patient flushes, breaks out into a drenching sweat, the blood pressure sinks, and the temperature falls. In one individual the rectal temperature dropped so low it could not be registered for several hours with a clinical thermometer, and two days later the observation was repeated with the record taken on a kymographic thermo-couple. The pre-injection rectal temperature of 98·8° dropped in the course of two hours to 93·8°, where it remained stationary for nearly two hours, and then slowly returned to normal.[*] The basal metabolic rate meanwhile fell from its pre-injection level of −27 to −50 when the temperature was at its lowest, and had only risen to −37 at the end of four hours.[19] When given subcutaneously in this patient the extract had no appreciable effect except as an antidiuretic. When given intravenously, as a control, it caused immediate pallor with no sweating and acted as a prompt purge; but the antipyretic response and effect on the metabolic rate was negligible. Corresponding reactions, though less marked, have been observed in other patients.

However these effects are to be interpreted, they at least indicate that we cannot safely ignore the possibility of some posterior lobe participation in the vasomotor and other activities of the interbrain. Whether there are other drugs that would act by way of the ventricle in this same vigorous way with the same promptitude is not known, but certainly the extract when so administered must act on the hypothalamic centres by direct absorption rather than by finding its way first into the blood stream, else, when injected intravenously, it would be expected to produce the same reactions with equal or greater promptitude.

But even should the "hypothalamists" grant that the posterior lobe way well enough be under the influence of the diencephalon now that the two have been shown to have histologically demonstrable neural connexions, they would still exempt the anterior hypophysis from any such control. As already pointed out, even the gonadal aspects of the adiposo-genital syndrome have been ascribed by them to hypothalamic injuries, and Smith, too, has included (1927) genital atrophy among the characterising features of the tuberal syndrome in the rat, leaving for the anterior hypophysis only the control of growth and the influence on thyroid and adrenal cortex. In all probability this gonadal effect is merely another instance of interference with hypophysial blood-supply, or of interrupted nerve-supply. Otherwise we could not possibly explain why precisely the same gonadal effects, produced by experimental ablations of the anterior lobe, can be effectively counteracted so long as replacement therapy is continued.[20] Moreover, the attribution to the tuber of an independent influence on the reproductive functions would appear to disregard the proven relation of the anterior lobe to these processes through a special hormone.

In short, it is highly improbable that these two corresponding effects should be produced, the one by an hypothalamic lesion, the other by removing the source of chemical messages, in the absence of any functional interaction. Though both are instances of deprivation effects, one paralytic, the other secretory, some light may be shed on the subject by recent observations, dealing with the activation rather than the inhibition of this particular neuro-

[*] A cubic centimetre of "surgical pituitrin" has been used in these tests.

[20] Smith, P. E.: Hypophysectomy and a Replacement Therapy. Amer. Jour. Anat., 1930, xlv., 205.

genital mechanism. To this purpose the rabbit lends itself particularly well, for, unlike rats and mice, it is a peculiarity of this animal normally to ovulate only after mating. The actual discharge of the ovum occurs after a lapse of 10 to 12 hours, this, as shown by Corner, being approximately the length of time it takes for ovulation to be artificially induced by the injection of the chemically isolated anterior-pituitary hormone of sex. To supplement this, Fee and Parks [21] have found that if the animal is decerebrated with inclusion of the hypophysis within an hour after mating the cycle will be interrupted, whereas if the decerebration is delayed for more than an hour, the normal process of ovulation will go on to completion. From this it is quite apparent that the copulatory act must set going some emotional and excitatory impulses which serve with promptitude to release the sex hormone from the anterior hypophysis. These impulses, arising in this way, could scarcely be discharged other than from that primitive structure, the interbrain, common to all mating species, and they either pass directly to the gland or, what is more likely, reach it in a more roundabout way through the sympathetic nervous system. Zondek speaks of the pituitary sex hormone as the motor that sets the reproductive cycle going, but the emotional self-starter is probably in the diencephalon.

Clinical Correlations.

We have so far, largely from an anatomical and physiological point of view, considered more or less separately the anterior pituitary, which is typically a gland of internal secretion, the infundibular lobe with its epithelial investment which has a secretory mechanism dissimilar from any other in the body, and finally the diencephalon, an all-important station for the transmission or possibly for the inauguration of vegetative and emotional mesages. And while discussing these separate parts stress has been laid, so far as possible, on their interdependence.

Though in modern times attention was redirected to this region of the wondeful rete by its tumours, our principal source of knowledge has been, as usual, the experimental laboratory where there are now so many interested workers, ably abetted be it said by the dog, the rat, the ox, and the pollywog, scarcely a day passes without some new disclosures. These may be in harmony or in discord with established views, and to correlate with clinical experience what knowledge the laboratory provides is often difficult, even baffling. This may be for want of that peculiar acumen or instinct that tells what at the bedside is worth recording, but it is partly due to the adaptability of the body to its pathological processes which may so effectually hide their symptomatic effects as to render them scarcely possible to detect. Endocrinology lends itself to two glaring faults, one the popularisation of writing on the subject, and the other a tendency of clinical observers to draw upon their fancy in a symptomatology which does not lend itself to precision.

The first thing with which one is forcibly struck in clinic and pathological laboratory is the frequency with which lesions that supposedly would throw the diencephalo-hypophysial mechanism wholly out of function may give, at least in the present state of our perception, no appreciable symptoms whatsoever. It is well known, for example, that in hydrocephalus the walls of the third ventricle become ballooned out to paper thinness and apart from the clinical tradition that hydrocephalic children are apt to be placed, good natured and well nourished, the 'tween brain appears to be doing its work well enough.

Even more striking is the fact that large tumours may come to fill the third ventricle, and so to distort its walls as to leave no recognisable trace of them, without the slightest symptomatic indication of any interference with the neurohypophysial mechanisms which have been so laboriously analysed. Should one wish to present further evidence that all of this talk about the hypothalamus and its functional importance is mere rubbish, the fact may be adduced that tumours of the third ventricle are far more often betrayed by ventriculography than by the neurological symptoms they provoke; and to make this still more emphatic, the further fact may be dragged in that under favourable circumstances tumours of this region may be successfully removed without provoking any of the symptoms heretofore discussed at such length. In two recent cases, by a transcortical approach through a hydrocephalic lateral ventricle a roentgenographically-demonstrated ependymoma filling the expanded third ventricle has, with much trepidation, I admit, been radically dissected out of its bed leaving a large, raw cavity with no subsequent trace of personality change, of polyuria, adiposity, somnolence, hyperthermia or vasomotor disturbance, one or all of which might well enough have been expected.

But negative observations such as these, however, disconcerting, need not be given undue weight. Positive findings when suitably marshalled are more important than any number of circumstantially negative ones; and when cases come to be analysed in sufficient numbers, there is found to be convincing testimony in abundance. There are two types of tumour of the region which from a symptomatic standpoint are particularly informative. They are the chiasmal gliomas and the congenital tumours of the hypophysial duct to which frequent allusion has already been made.

THE CHIASMAL GLIOMAS.

These tumours, though less common than the craniopharyngiomas, provide an important contrast not only in that they are invasive and destructive but because they primarily involve the region of the supraoptic nucleus, whereas the congenital tumours produce their effects by pressure distortion and are more likely to implicate the hypophysis and the tuberal region.

A report upon these chiasmal gliomas, largely from an ophthalmological standpoint, was made in 1923 in collaboration with Dr. Paul Martin, at which time we had little to say of their tendency to invade the ventricle. In this respect to be sure the tumours differ greatly, for some of them are relatively benign types of glioma which fail to provoke recognisable diencephalic symptoms, whereas others of a more malignant type soon involve the anterior wall of the ventricle, and may in time wholly obliterate its cavity.

When one comes to review the clinical histories of the 22 cases in which such a tumour has been histologically verified, it is not surprising that the older records are found wanting in respect to some of the points on which greater emphasis might be laid to-day, rapid loss of sight having been the urgent symptom to which chief attention was naturally paid. Nevertheless, polyuria was observed in nine instances (six of them being recorded as diabetes insipidus with a daily output of *circa* five litres), and in only four cases was it expressly stated that there was no

[21] Studies on Ovulation, Jour. Physiol., 1929, lxvii., 383.

polyuria. Adiposity was noted (or the photographs of the patients indicate its presence) in eight instances, and in three there was notable obesity. Though one of the obese patients showed excessive polyuria, most of those with pronounced diabetes were, on the contrary, thin and tall; one of them, a recently observed case, was a spare young man, aged 23, six feet three inches in height, with marked diabetes of over three years' duration. In another instance, a boy 13 years of age with marked diabetes, the emaciation had become extreme.

Undue sleepiness, occasionally described as somnolence, was mentioned in six instances. The systolic blood pressure was 110 or below in the majority of the cases, the basal metabolic rate was subnormal in the nine patients on whom it could be taken, and the five early postoperative fatalities were all attributable to, or at least associated with, extreme terminal hyperpyrexia.

Occasionally one of these gliomatous tumours may evoke a definite "march" of symptoms which suggests a progressive involvement of the diencephalic centres. Of this the following is an example:

A previously healthy pre-adolescent school girl resident in New York, an only child, 13 years of age, in October, 1929, acquired an oculomotor palsy on the right eye and soon after was found to be blind in that eye. She was taken to a hospital, where on X ray evidence the diagnosis of a suprasellar tumour was made. Questioning brought out the fact that antecedent symptoms of polydipsia and polyuria had long been present; that during the summer of 1929 she had suddenly grown quite stout (her exact weight had not been taken); and that she had been withdrawn from school that autumn because of abnormal sleepiness (12 to 16 hours a day). Vision shortly after became impaired in the other eye, and soon the child showed a marked change in personality. It was difficult to induce her to take nourishment, she became uncontrollable, and soon acquired an unaccountable fever ranging from 101° to 104° F. which persisted for ten weeks up to the time of her admission to the Brigham Hospital.

On admission (Jan. 25th, 1930) the child proved to be more like a wild animal than a human being. She would lie quiet and apparently somnolent unless approached or touched when, as Dr. Oldberg's record expresses it, "she would become suddenly galvanised into tremendous hyperactivity." She would utter a succession of piercing shrieks, would thrash violently about the bed, meanwhile clawing and scratching at her attendants. Most of the time she was wholly irrational and incontinent and only after prolonged coaxing could she be persuaded to take food or drink. She was found to have: (1) a primary optic atrophy with apparent blindness; (2) a normal sella turcica without suprasellar calcification; (3) a persistent pyrexia without accompanying leucocytosis; (4) a pulse-rate of *circa* 140 with arrhythmia; and (5) an oliguria rather than a polyuria, so far as could be determined. There certainly was no polydipsia.

The child remained in this hopeless state with conditions unaltered for the next three weeks. An exploration offered little but was finally undertaken on Feb. 18th, when a soft glioblastoma of malignant type involving the chiasm and spreading widely into the ventricle was disclosed. A considerable mass of this tumour was sucked out and radium seeds implanted. There was subsequent hyperthermia and she died 48 hours later with a rectal temperature of 108°.

Here, then, was a case in which disturbance of water and fat metabolism, of thermal regulation, of sleep, and possibly of the vasomotor mechanism were finally all obscured by the removal of cortical inhibitions which left the patient in a state quite comparable to the "sham rage" described by Cannon and others in decorticated animals. All these symptoms, it will be observed, may well enough be looked upon as purely diencephalic in origin, with no obvious bearing on the pituitary body whatsoever. As a matter of fact, since three out of every four of the recorded chiasmal gliomas occur in childhood, since many of them pursue a rapid course, and since the hypophysis does not become directly involved in the process, secondary disturbances of growth and maturation are inconspicuous or wholly absent from the clinical picture.

THE CRANIOPHARYNGIOMAS.

In contrast to the foregoing, the symptomatic sequence in the congenital hypophysial-duct tumours is more slowly progressive. The effect of the lesion upon the secretory activity of the anterior hypophysis is ordinarily evident from the outset, and owing to the usual point of origin of the lesions they come to exert their pressure effects against stalk, infundibulum, tuber, and chiasm from behind and below rather than from in front as do the invasive gliomas just considered.

A systematic review of 80 of these cases that have been histologically verified, however disheartening from a neurosurgical standpoint, for they represent one of the most baffling of neurosurgical problems, yet provides a fruitful source of study of diencephalo-hypophysial symptomatology. As already mentioned, these tumours vary greatly in position, size, distribution, histological character, age of symptomatic onset, and ultimate complications. They may be minute, pea-sized cysts, or huge, calcareous masses the size of a tennis ball; they may originate and remain confined within the sella or, what is more common, lie wholly above it and consequently they are, most of them, lesions that compress the tuber and hypophysial stalk early in their course.

Two of the constitutional features characterising the syndrome of Fröhlich—namely, the retardation of growth and adolescence—are sufficiently well explained in the young patients by the interference, through compression, with the normal secretory activities of the anterior hypophysis. An explanation of the adiposity is less clear, and the fact that it often occurs in the absence of polyuria shows that these two symptoms do not necessarily go hand in hand. Indeed, patients with a tumour confined within the sella, as is true of the adenomas, often show adiposity when the tuber could hardly have been affected.

The age-distribution of these cases at the time of their hospital admission has been by decades as follows: 15 in the first; 27 in the second; 15 in the third; 10 in the fourth; 7 in the fifth; 4 in the sixth; and 2 in the seventh decade. By far the more striking symptoms occur in the younger groups, in which evidence of anterior lobe impairment is shown by delayed growth or actual dwarfism and by retarded maturity or persistence of actual infantilism. Most of these younger patients at the same time show a tendency to be over well nourished, or they may be actually obese. This, however, is not invariable, for some of them are actually thin or emaciated; and others become definitely progeric in appearance, suggesting the gradually developing cachexia observed by Smith in his hypophysectomised rats.

Some of these purely anterior lobe symptoms may be carried over from early life to the third decade, but this is unusual, for the almost inevitable secondary complication of hydrocephalus ordinarily serves to end the story before this. When, on the other hand, symptomatic evidence of the lesion, usually signalised by a disturbance of sight, is postponed to the third decade or later, growth and development may have been normal in all respects. Amenorrhœa, or, in the male, sexual dystrophy, then usually puts in an appearance, but under certain circumstances depending on the site of the lesion even these indications of anterior lobe involvement may be wanting. Our most recent case provides, through a sorry experience, an example of this.

A woman 27 years of age (Surgical No. 35994), having previously enjoyed normal health, was married in January, 1925, and soon became pregnant. At the time of parturition expulsion was impossible, and after a prolonged labour recourse was had to a forceps delivery which the child did not survive. In spite of no nursing, she continued to lactate for twelve months. Three years later, at her second pregnancy, precisely the same sequence of events occurred. Following this, she became hypersomnolent and showed marked mental changes accompanied by periods of fright that were regarded for some months as a post-partum psychosis until the presence of a frontal tumour was finally suspected.

On admission to the hospital she was found to have a choked disc of six diopters associated with suprasellar calcification and secondary hydrocephalus, possibly accounting in part for her mental changes. Perimetry was precluded; also the metabolism estimation. Her temperature was subnormal, registering 96° F. on one occasion. The blood pressure was exceedingly low, 80 systolic over 40 diastolic. Her skin showed a blotchy pigmentation. There was no adiposity or polyuria.

At the operation a subchiasmal tumour was disclosed and in the hope of thereby relieving the hydrocephalus its calcified portion was dislodged and an overlying cyst emptied. From this operation she never regained consciousness and died 24 hours later, apparently from cardiac complications without hyperthermia. A comparatively small cystic tumour, chiefly involving the tubero-infundibular region with intact pituitary body and stalk, was found at autopsy.

Here, then, is an example of a craniopharyngioma situated in the tuberal region that had given no symptoms of any sort till the third decade and even then none that could be ascribed either to diencephalon or to hypophysis, unless possibly the repeated difficulties of parturition can be ascribed to imperfect uterine contractions from want of posterior lobe secretion. As an offset to this case, one in which pronounced diencephalo-hypophysial symptoms first put in their appearance even later in life may be cited:

The patient, 46 years of age, a classical scholar holding a professorial chair, had always enjoyed excellent health, had been married for fifteen years, and was the father of three children whose ages were 14, 11, and 8 years respectively. His height was 5 ft. 9 in.; his average weight had long been stationary at about 182 lb.

Some six months or so before his hospital admission (viz., Oct. 3rd, 1928) he began to experience a subjective blurring of vision. Soon after this, in uncertain sequence, he became impotent, extremely drowsy, acquired an abnormal thirst with evident polyuria, and definite personality changes were soon observed.

Examination.—The patient was quite indifferent to his breakdown, bored by the neurological tests and note-taking, and though polite and serene if aroused, if left alone tended to drop off to sleep. He was occasionally incontinent and was once found in bed between the sheets with his boots on, fully dressed. The fundi were regarded as normal in spite of the presence of a large central scotoma in the left eye and a lower temporal defect on the right. There was unquestionable diabetes insipidus, his polyuria averaging from four to five litres daily. He was, perhaps, over well nourished but not more so than might have been expected of a man of his age accustomed to a sedentary life. The basal metabolic rate was −32 per cent. The sella turcica was of normal size and contour. The examination otherwise was quite negative and ventriculograms were interpreted as showing normal conditions.

The patient remained under observation for a month with the nature of his lesion undiagnosed, and as he was evidently deteriorating a transfrontal exploration was finally made on the assumption that a suprasellar tumour of some sort must be present. A solid craniopharyngioma was disclosed (on Nov. 5th, 1928) largely underlying the chiasm, which was pushed upward. The better to expose the lesion, the chiasm was split anteroposteriorly whereby the anterior third ventricle and supraoptic nucleus could scarcely have escaped injury.

From this operation the patient made an excellent recovery with improved visual acuity in spite of the permanent bitemporal hemianopsia to which he was committed. Instead of there being an increase in the polyuria it definitely and progressively diminished, and at the time of the patient's discharge (Nov. 26th, 1928), three weeks later, the intake and output had dropped to about 1500 c.cm. daily. Meanwhile, instead of gaining weight he had lost, from 191 to 175 lb.

He subsequently attempted to resume his college duties but it was too much for him and he spent most of his time in sleep during the winter and spring, there being occasional periods of transient polydipsia but no gain in weight. During the summer he was much better, quite like himself for the first time since the onset of his malady, but by the end of September he had again become so somnolent he would sleep 20 hours out of the 24. A month later pressure symptoms set in, with headache, vomiting, rigidities, Cheyne-Stokes respiration, slowed pulse, and on Nov. 26th, 1929, came the end, scarcely more than 18 months from the first observed symptom.

The emotional negativism shown by this man is highly characteristic of these particular lesions and stands in marked contrast to the violent psychomotor agitation ("sham rage") in the patient with a glioma previously described. Between the negative and positive emotionalism shown by these extreme types there are countless gradations that have long excited the interest of neurologists and psychiatrists.

The tumour in this particular case, a non-calcified though largely solid type of craniopharyngioma, not only filled the entire interpeduncular space, but projected into without enlarging the sella turcica, the pituitary body having become greatly compressed. The notable symptoms were impotence together with diabetes insipidus and moderate adiposity, both of the latter subsiding as the malady progressed, an increasing somnolence being the major terminal symptom. Tumours fully as large as this, however, may cause scarcely any appreciable symptoms and would remain practically silent were it not for the customary disturbance of vision from involvement of the chiasm and the terminal manifestation of hydrocephalus.

It would be superfluous to cite further clinical examples of diencephalo-hypophysial symptomatology. These few may well suffice. Here in this well-concealed spot, almost to be covered by a thumb-nail, lies the very mainspring of primitive existence—vegetative, emotional, reproductive—on which, with more or less success, man, chiefly, has come to superimpose a cortex of inhibitions. The symptoms arising from disturbances of this ancestral apparatus are beginning to stand out in their true significance. That the older literature proves to be filled with reports of cases as telling as any of those that I have cited goes to show that we have advanced no whit in powers of observation, merely that modern science has permitted us to give to them revised interpretations.

Final Argument.

There is indeed nothing wholly new under the sun; what appears to be new is no more than something old in a novel aspect. In support of this, and before attempting to assemble the arguments favouring the interdependence of diencephalon and pituitary body, I may be permitted a quotation from the writings of one of your countrymen, a seventeenth century physician and anatomist:[22]

"Seeing therefore there is such an affinity as before mention'd, between the *Rete Mirabile* and *Glandula Pituitaria*, and taking it for granted, that the office of the *Glandula Pituitaria* is not what it hath generally hitherto been believ'd, to the end we may attain a more exact knowledge of what it really is; it seemeth not altogether immethodical to take that part into consideration in the next place, together with the *Infundibulum*, which last hath not only as near a relation to the Gland as the Gland hath to the *Rete*, but such a close communication with it, that *it seems in a manner almost impossible to treat of one independently of the other.*"

The italics are mine, but the conception that pituitary gland and adjacent third ventricle can scarcely be considered separately is far from being so; and it may not be "altogether immethodical" in

[22] Ridley, H.: Anatomy of the Brain, London, 1695.

closing this address to supplement the statement made by Humphrey Ridley over two centuries ago by newly acquired, though at times somewhat contradictory, testimony, derived at many hands from diverse sources—evolutional, morphological, biological, pathological, and clinical.

The pituitary body is a combined neuro-epithelial organ present in all craniates. Its purely epithelial lobe is the first of the endocrine organs to be differentiated in the embryo; its neural portion is an outgrowth of the oldest part of the brain to be laid down. If the rudimentary organ is removed from the amphibian embryo its further growth and metamorphosis are promptly checked; if reimplanted, these effects do not occur, but the rudiment will not long remain functionally active unless neural tissue is included in the transplant. The infundibular lobe is an expansion of that ancient portion of the cerebrum, the diencephalon, which retains its simple structure in all creatures that can boast of a brain at all. Herein lie ancestrally important mechanisms common to all species which have to do not only with their vegetative functions, but with their primitive instincts—in mating, in satisfying hunger and thirst, in restoration from fatigue by sleep, in regulation of body temperature, in self-protection by combat or escape. From the diencephalon non-medullated nerve-fibres pass direct by way of the infundibulum to be distributed in the posterior lobe and its epithelial envelope. Extracts of this lobe contain a peculiarly active substance or substances, the injection of which serves to counteract one, at least, and probably more than one of the symptomatic effects of irritative or paralytic injuries to the suprajacent interbrain. Non-medullated nerve-fibres also connect this ancient station by way of the spinal cord and the sympathetic nervous system not only with the thoracic and abdominal viscera but some of them even turn back to act upon the anterior hypophysia itself. Hence diencephalic messages may be relayed to this somewhat insulated part of the gland on whose hormones depend not only normal body growth and the normal function of certain subsidiary endocrine organs but, indeed, the very perpetuation of the species. For without the presumably emotional discharge from this source of the hormone of sex, the chain of events leading to the escape, fertilisation, and implantation of the ovum cannot take place.

Though information may be gained by the independent study of its separate parts, physiologically the diencephalo-hypophysial mechanism can only be properly interpreted when looked upon as a whole and even then only when its influence on the entire organism is taken into account. So, at the end, I may appropriately quote what Thomas Willis said of that "divine artifice," the *Rete mirabile* and its function: "There is nothing in the whole fabric of an animal body more worthy of admiration . . . . nothing can be conceived as more skilful, and nothing which argues more forcefully the providence of a divine Author."

Corrigendum.—On p. 125 of THE LANCET last week in the footnote (No. 13) the names of Prof. G. Popa and Dr. Una Fielding were mis-spelt.

THE HOSPITAL SHOPPING BUREAU.—This organisation, which was established by the British Charities Association to assist the smaller hospitals to buy on the best terms possible, is to be shut down. It was pointed out by the National Chamber of Trades that the scheme was prejudicial to local retail traders who are constant in their support of the hospitals.

THE USE OF AVERTIN IN CHILDBIRTH.

BY J. S. M. CONNELL, F.R.C.S. EDIN.,

LATE OBSTETRIC AND GYNÆCOLOGICAL OFFICER, DUDLEY ROAD HOSPITAL, BIRMINGHAM.

THE use of anæsthetics and analgesics in labour has been for long a matter of much argument, beginning on the day when Sir James Simpson courageously and dramatically eased the pains of labour for a royal patient. No humane practitioner would take the negative side if the means were to his hand, but hitherto the adverse arguments have held the field, mainly because of the absence of such means. At the present time, when much attention is focused on the history and development of midwifery, it has been shown that we cannot congratulate ourselves on its progress when compared with the sister arts, Medicine and Surgery. The reasons are not far to seek. First comes the inertia and conservatism associated with a fatalistic agreement that "man is born to trouble as the sparks fly upward." In this case it is *woman*, and since, till comparatively recent years, women's knowledge of the sciences and arts associated with medicine have been negligible, womankind has had to suffer in travail unassisted, except by the encouragement of the tender-hearted but non-understanding medical man, and the knowledge that the pain will not last for ever. Secondly, there is the fact that midwifery is very poorly paid. The result is that the older and more experienced practitioner tends to avoid it as much as possible, leaving the bulk of it to his junior, with his way to make and his experience to gain. Apart from the pain, which has been well described as "devastating," in the majority of cases of childbirth the course is physiological, and the larger number of patients will not and frequently cannot pay a fee at all commensurate with the care and anxiety required to make sure of a successful termination to labour. But the third and most important reason is connected with just that humanity and pity which is common among the medical profession. The cries of the patient, the trepidation of the husband, and the urgency of the woman's mother combine to urge the doctor to *hurry*, with many and various regretful sequelæ. The first two reasons will remain, I fear, for some time, but the third may be removed.

Apart from the actual difficulties of labour, there are associated questions which may be influenced by the administration of something to ease the pains. I believe that the results of the normally "devastating" pain of a first labour are far reaching. They include the wish to avoid further pregnancies, thus destroying the perfection of marital relations. They encourage the resort to various noxious or mechanically harmful contraceptives; and they frequently lead to the use of abortifacients, with their far-reaching pathological effects. In the end they lead to an unstable and anxious mentality which is very common in the ranks of those wives who have ambition to make something out of life higher than merely existing from day to day. Such observations were very impressive during five and a half years while I was in charge of a large gynæcological and obstetric department in a poor-law hospital, to which many of such cases eventually came.

The Available Agents Reviewed.

I am convinced that any agent which would remove or mitigate such memories of the first labour would also remove or mitigate some of these distressing

results. No such agent is worth anything unless it can be used by the general practitioner. Midwifery is, and will be, in his hands for some time to come. In hospital practice, and in well-paid nursing home practice, various means are at the disposal of the specialist. Scopolamine and morphine, or intermittent gas and oxygen, can be used with quite good results. But the former entails many visits to the bedside, and the latter may mean a sederunt of 8 to 12 hours—both quite impracticable for the general practitioner. The use of rectal ether has been associated with so much well-grounded adverse criticism that I have never tried it. Of course chloroform has remained the standby, but here again the practitioner must be present the whole time, and take the chances of chloroform poisoning, or confine its exhibition to the last few pains, which is not by any means enough to attain the end in view.

The introduction of avertin seems to give hope that at last we have something that fulfils the requirements. These are: (1) Safety. (2) Ease of administration. (3) Effective mitigation of pain for a sufficient period. (4) Absence of after-results to either mother or child. (5) Absence of undue prolongation of labour. (6) Portability. Avertin was introduced on the Continent, and I know of no literature in this country dealing with its use in labour. Like all such novelties, it had to find its place as regards indications, dosage, &c. The German literature, however, was so convincing that I experimented, and although even now I have only used it in a few more than 50 cases, in these it has fulfilled the requirements outlined above in a marked degree. Most of the work, both abroad and by myself, has been in hospital practice, but enough has been done in private to establish the usefulness of the drug.

Indications.

Avertin may be used in every case where the antenatal examination has given expectation of normal parturition, except if the presenting part is on, and stretching, the perineum. In such cases whiffs of chloroform are indicated. In abnormal cases, such as malpresentations, the abnormality, of course, has to be rectified, but unless definite operative measures have to be instituted, requiring a deep anæsthesia with great relaxation, avertin is useful in allowing time for the natural forces to come into play, for example in slowly rotating posterior presentations or in the operation of version and bringing down a leg. A marked disproportion between the head and the pelvis is probably an indication for Cæsarean section, but if this is contra-indicated, here again avertin will allow time for the cervix to dilate fully, and for as much moulding to take place as possible, before attempts are made to deliver, whether after perforation or not.

It is in primiparæ that the greatest use of avertin is found. All multiparæ will agree that the first was infinitely worse than subsequent labours. I was at first frequently too late in administering the injection to multiparæ. Once full dilatation is reached in them, and the waters have broken, the head frequently comes on to the perineum at once, and makes the injection difficult or impossible. A rather different

TABLE OF TYPICAL CASES OF CHILDBIRTH WITH AVERTIN.

No.	Age.	Labour commenced.	Two-thirds dilatation. Avertin given.	Drowsy in minutes.	Pulse—		B.P.		Child born.	Parity.	Reaction of mother.	Condition of child.	Intervals of contractions in minutes.	Milk.

a. and p. = a.m. and p.m.

Notes of Cases.—CASE 6. Albuminuria with marked œdema. CASE 7. Very long first stage—over 24 hours. Patient had morphia twice. CASE 8. Version under general anæsthetic, with induction of labour, for breech presentation with contracted pelvis. Prolonged first and second stages. CASE 10. Albuminuria. Long second stage. Action of avertin lasted for six hours, but thereafter patient fully conscious of contractions and pain. Dose should have been repeated. Child showed no effects.

time of administration must, therefore, be chosen in treating primiparæ and multiparæ.

A Typical Case.

The course of a typical case of avertin anæsthesia in a normal primipara is as follows.

The patient commences labour and either goes into hospital or nursing home, or sends for the doctor and midwife. As soon as a show or one finger dilatation of the os, with good regular contractions, has established the diagnosis, a quarter grain of morphia is given. Less morphia should not be given, as in some cases it has only the effect of increasing the excitement and distress of the patient, and strengthening the contractions. In a few cases another sixth of morphia is required, especially in primiparæ over 30, but commonly the effect lasts until a quiet dilatation has taken place in 6 to 12 hours. Occasional examination per rectum will give an indication of progress, but these are mostly unnecessary. Membranes of a normal toughness with a well-fitting head will not rupture until the os is about two-thirds dilated and on this rupture the doctor should again be called. At this point also the patient begins second stage pains, bearing down and complaining of severe backache. This is the time to give the avertin, and not before. The patient should be allowed to realise the severe pain that accompanies the descent of the head, in order that she may more fully appreciate the benefit of the comparative ease thereafter. With multiparæ, the optimum time for giving the avertin is less exact. It is better to anticipate the rupture of the membranes. In many cases there will not be time to give the preliminary morphia, and it is less necessary here. Avertin should be given when the cervix is fully half dilated. if the contractions are strong and regular. If they are not it is as well to wait until they are—probably another hour or so. The patient is then left to herself, the doctor having satisfied himself during half an hour that the pulse-rate, the respiration-rate, and, if he likes, the blood pressure are in good order. The administration of avertin may be accompanied by a short period of excitement if, in multiparæ, a previous injection of morphia has not been given. But this does not last more than five to ten minutes, and is usually entirely absent after morphia. The patient is asleep within five minutes in the majority of cases, although she may be roused to speak.

It is generally recognised that morphia should not be administered within two hours of the birth of the child, and avertin should not be given until two hours have elapsed after the morphia. The action of morphia in childbirth is very variable, but the usual slow dilatation in primiparæ gives ample time for such intervals to be attained. The rare case of precipitate labour in a primipara is easily recognised by the early prolonged and powerful contractions, and by the fact that the cervix is much further dilated than usual when first the doctor sees the case. It would then be treated like a multipara and the morphia omitted.

It is obviously of benefit to carry out all subsequent procedures quietly and gently. In nervous and excitable people full sleep may not ensue for 10 to 20 minutes. In certain cases in hospital and most cases in private, I have returned shortly before the "crowning" of the head, to give either a few drops of ether, or gas and oxygen, in order that the patient may have no recollection whatever of the birth of her child. In primiparæ this is useful, but in multiparæ quite unnecessary. If it is omitted, however, and the effect of the avertin is diminishing, the patient may become very restless and even uncontrolled during the passage of the head over the perineum. This has in a few cases made it difficult to "support the perineum" (a process which I consider really useless).

Technique.

The technique is simple. The apparatus required consists of: (1) a graduated glass cylinder to hold about 300 c.cm., with cork for same; (2) a small measure, say 10 c.cm.; (3) a funnel with tubing about three feet, ending in a glass connexion to join with (4) a No. 6 catheter; (5) a thermometer, F.; (6) a small bottle of 1–1000 Congo red solution; (7) a bottle of distilled water, say 1000 c.cm.; (8) avertin fluid.

The preparation of the injection is as follows:—

Into graduated measure (1) put about 160 c.cm. distilled water. By immersing this in a jug or other vessel of hot water, raise the temperature to 100° F. Measure 0·075 c.cm. of avertin fluid per kg. of body-weight. (This has frequently to be guessed, but it is not essential to be exact.) For example, 9 st. equal 126 lb., equal roughly to 60 kg. Sixty times 0·075 c.cm. equal 4·5 c.cm. Add this to the distilled water, insert cork and shake vigorously. (It is important first to raise the temperature to 100° F., or solution is delayed.) Take a few c.cm., say 5, of solution back into the small measure and add a couple of drops of Congo red solution. The colour *must not* change. I have never found a blue discoloration, showing presence of free dibromacetaldehyde. The temperature should again be raised to 100° F., and the solution is ready for use. Just after a good long strong contraction has passed, a catheter should be inserted high into the rectum and about 50 c.cm. run in fairly quickly. When the next contraction comes it is usually a small one, but strong pressure must be made round the anus, and the patient told *not* to bear down, or much of the fluid may be lost. There is seldom any difficulty in retaining the bulk of it.

After the first contraction is over, the rest of the avertin solution should be passed in, the process extending over about 15 minutes, and firm pressure being applied to the anus during a pain. By this time, however, the patient is probably asleep and does not bear down strongly. The fluid soon makes its way up past the point where the child's head is pressing on the rectum, and after about half an hour from the commencement of the injection there is no tendency for any to return.

The Advantages of Avertin.

It is necessary to examine how far this procedure fulfils the required conditions.

1. *Safety.*—The dosage I have used, 0·075 c.cm. per kg. body-weight, is well within the safety limits, according to my own experience and the literature. For general surgical practice 0·1 and even 0·125 c.cm. have been used, with good results reported. But such doses are unnecessary in labour and should not be used. I have never had a moment's anxiety about the condition of the patient. The table of typical cases shows a small increase in the pulse-rate. The blood pressure drops very shortly after the administration, but only slightly in most cases. Prof. W. Benthin, of Königsberg, reports a drop of 10–20 mm. Hg in 25 per cent. of cases, 30–40 in 25 per cent., slightly more in several, and in 19 cases the fall was 60 to 100. My cases have never gone so low as the latter, and even in his, with larger doses, the fall has been of short duration. It quickly returns to a few mm. Hg below normal. The patient, however, is in a very deep sleep, similar to alcoholic coma, and must not be left alone. Any good midwife may be left in charge to see that no respiratory interference is brought about by the patient's movements such as bending the neck or burying the face in the pillow.

As regards the child, in two cases I had to use forceps, since the head had lain long on the perineum, and the beat of the fœtal heart was lost. But this may happen in a non-anæsthetic labour, and in both cases I was over anxious—one was that of a doctor's wife. Here the delay was rather due to the excessive use of morphia and gas and oxygen. In one other case my assistant had a similar experience. In all three cases the child cried lustily immediately, and after birth showed no effects whatever.

2. *Ease of Administration.*—This has been fully explained in describing the technique. There are no "snags," except the partial return of the injection if run in too rapidly, and if the anus is not controlled.

3. *Effective Mitigation of Pain for a Sufficient Period.*—Avertin, in the obstetric dosage, is not an

analgesic or full anæsthetic. The patient, under the doses I have used, is conscious of the stronger contractions and of *some* pain, and frequently bears down strongly. Between pains, however, she is fast asleep, and thus avoids what I think is the main cause of distress and shock—namely, the constant intercontraction sacral pain. Apprehension is also removed, giving mental rest. The duration of action of avertin varies, like everything else in labour. Prof. Benthin gives 1 to 1½ hours for narcosis deep enough for major gynæcological operations. Prof. E. Martin, of Elberfeld, with a dose of 0·6 c.cm. per kg. body-weight, gives 1¾ hours in cases of childbirth; but I have found the effective duration much longer. The dose may be repeated, however, with safety, and Mr. C. C. Coghlan, of Sydney, has reported eight cases where three doses were given with no bad after-effects. But for the busy general practitioner I think one administration may suffice, and at least give a sufficient duration of action to prove a very valuable aid. I have never yet repeated the dose, contenting myself with giving whiffs of chloroform or ether for the final pains, if necessary.

4. *Absence of After-results to Mother and Child.*—The condition of the child is generally better than after an ordinary unassisted labour. In two cases the child has been somewhat sleepy, but in all the others it cried at once and behaved thereafter normally. One stillbirth was due to excessive moulding of the head with intracranial hæmorrhage. There is no such anxiety as is usually present after scopolamine and morphine. This factor alone made me unwilling to continue to use that method. Mr. Coghlan reports one case out of eight where the child was born "slightly blue and sleepy" after avertin. As to the mother, one case, that of the doctor's wife above mentioned, had paresis of the bladder leading to temporary retention. As this is by no means unknown in normal cases, I scarcely like to blame avertin for it. In all other respects the condition of the mother has been excellent. She is not exhausted. She sleeps naturally for some hours after parturition, and awakes apparently in normal healthy condition. No delay in the milk flow was noticed. Involution of the uterus was not affected. Since in most cases the use of avertin has avoided forceps the vaginal and vulval condition is improved.

5. *Absence of Undue Prolongation of Labour.*—It is here that antagonists to any form of anæsthesia make their most important point. The ground for such objection appears to me somewhat unstable. The duration of normal labour varies within such wide limits, owing to such varying factors, that any small prolongation is of little importance. Much is made of the want of "bearing down" by the mother. But the most perfect parturition I have ever seen was in a patient who had transverse myelitis, where no bearing down and no pain were present. The uterus is normally quite able to expel its contents unassisted by other means, and the absence of bearing down is an asset rather than detrimental.

The figures for prolongation of labour due to avertin, however, are not serious. Prof. Martin gives an average for the second stage (I do not completely understand where he places his initial point) as 3·7 hours for unassisted labour, and 4·6 hours with avertin. Mr. Coghlan's average for total duration of labour is 14 hours, and he uses more avertin than I have recommended. My figures show that labour is prolonged, but in no degree to affect the child, and so long as the mother is quiet and easy, only the doctor's time has to be considered. If the above technique and arrangement of dosage are carried out, this loss of time may not be serious. The third stage of labour is not delayed, except in such cases as delay may be expected for other reasons.

6. *Portability.*—The apparatus goes easily into a small hand-bag, and a fairly large size midwifery bag will accommodate everything without difficulty.

Conclusion.

In conclusion, it might be stressed that the use of avertin in childbirth, in my hands, has not given a painless labour. Nothing short of full anæsthesia will do so. But with avertin it is possible to make things so easy for the patient that she has no devastating pain, no prolonged backache, no exhaustion, and no memory of a terrible experience to jaundice her outlook on life. Prof. Martin recommends the solution of avertin in milk instead of distilled water, and says that the duration of action is thereby considerably prolonged. I have not used this to any extent, and have found the simpler method satisfactory enough. It has been noticed that the uterus is rather less firmly contracted at the end of the third stage than is usual in primiparæ, and that the loss may be rather more free. This has never given rise to any anxiety, and but seldom calls for an injection of pituitary extract, which, of course, is not given as a routine in primiparæ. In all the cases at which I have been present I have left the patient with perfect confidence, in the charge of an ordinarily trained midwife, immediately after the end of the third stage. There is no such laxity of the musculature as is seen after chloroform administration, and any slight laxity which may be due to the drug is probably compensated for by the absence of exhaustion and shock.

My experience leads me to think that this method of easing the pains of labour is worthy of trial by the general practitioner. It is not fool-proof but a very little practice is all that is necessary, and even a faulty administration, where much of the solution has been returned, has proved of benefit.

COMPARATIVE RESEARCHES ON THE GALACTOSE AND LÆVULOSE TEST FOR HEPATIC EFFICIENCY.

BY A. W. ELMER, M.D.,

AND

M. SCHEPS, M.D.

(*From the First Medical Clinic of the Hospital, Lwów, Poland.*)

THE administration of galactose and lævulose for estimating hepatic efficiency has been largely used by different clinics. Bauer and Strauss's method of detecting galactosuria and lævulosuria involves a renal factor, and many workers, therefore, prefer to examine the blood-sugar curve. Some, however, (Bauer, Kahler and Machold, Noah, Davies,[1] Meller and Frisch,[2] and others) prefer the galactose tolerance-test, and others (Strauss, Schirokauer, MacLean and Wesselow, Spence and Brett, Hetenyi, Tallermann and Kennet, Finkelstein and Dannenberg, King[3] and others) use the lævulose tolerance-test. The clinical value of galactose and lævulose has been discussed

by Lepehne,[4] but no comparative researches have been published.

We have made comparative researches on these two tests to find whether they have a comparable clinical importance, or whether one of them is better, and which is the more reliable tolerance-test of hepatic efficiency.

Technique of the test.—In every case, after a thorough clinical investigation, we examined the fasting blood-sugar and then gave the patient 40 g. of galactose in tea. Then, at half-hourly intervals for two hours, we tested the blood-sugar by the micro-method of Hagedorn-Jensen. At the same time during a period of six to eight hours we collected the urine and determined the percentage of sugar in it by polarimetry. Two days later we repeated this test with 45 g. of lævulose. Then we performed the test with tetrachlorphenolphthalein according to the method of Rosenthal and Kunfi, by injecting 5 mg. per kg. of body-weight. Later we tested the blood to find the dye retention in the serum. Moreover, we determined the bilirubin in the blood-serum quantitatively according to Hijmans van den Bergh, and examined the urine qualitatively for the urobilinogen reaction.

Like Kahler and Machold, we considered the galactose test positive if the blood-sugar had risen over 30 mg. per cent. We find the examination of the galactose in the urine insufficient, as we have noted before,[5] since we have found seven cases in which the rise of blood-sugar far exceeded 30 mg. per cent., yet there was little or no sugar in the urine.

Opinions differ more about the lævulose test. According to some workers the rise of sugar in normal cases does not exceed 10 mg. per cent., after giving 40–50 g. of lævulose (Schirokauer, Isaak, MacLean and Wesselow, Spence and Brett); on the other hand, other writers (Tallermann and Kennet, Greene, Snell and Walters,[6] Brown,[7] and others) say that it may rise much higher, and they consider the lævulose test to be positive only after a rise of blood-sugar to over 30 mg. per cent. We have stated that in normal cases the highest rise of blood-sugar is 20 mg. per cent., and that is why we consider the lævulose test as positive when this figure is exceeded. We need not add that the examination of lævulosuria after 45 g. of lævulose has been given is completely deceptive. The variation in the rise of blood-sugar after the lævulose is to be explained as due either to impurities in the lævulose or to unsuitable methods of storing it,* or to variations in its absorption from the mucous surfaces.

A NEW INVESTIGATION.

We have investigated 41 cases of hepatic inefficiency. The value of the galactose and lævulose tests appeared in this series to be identical. In 14 cases, however—that is in one-third—the results were different. The height and duration of the rise in blood-sugar after the administration of galactose was not parallel with the curve of lævulose; the blood-sugar curve was flatter after the lævulose than after the galactose in five cases, while in three the lævulose test was slightly positive, and in four it was completely negative. Only in one case was the lævulose test positive (+39 mg. per cent.), with a negative galactose test (+28 mg. per cent.).

Consequently, we consider that the galactose test is better than the lævulose test. The metabolism of galactose, unlike the metabolism of lævulose, is performed primarily with the coöperation of the liver and not with other tissues (Fischler [8]). We do not wish to assert that the galactose test is always sure, but so far as we know galactose metabolism depends not only from the condition of the liver but also on the capacity of assimilation of other tissues (Achard and Desbouis[9]).

* We administered the lævulose of Schering, which was preserved in a dark jar hermetically sealed.

SUMMARY AND CONCLUSIONS.

The galactose and lævulose tests do not agree in one-third of all cases of hepatic disorders. In some cases the lævulose test in the presence of a positive galactose test is slightly positive or completely negative. The galactose test is very much more valuable than the lævulose test in the diagnosis of hepatic disorder.

PUERPERAL INFECTION:

A BACTERIOLOGICAL STUDY.

BY ADAM L. K. RANKIN, M.D., D.P.H. EDIN.,
SENIOR MEDICAL ASSISTANT, EDINBURGH CITY FEVER HOSPITAL.

IT is generally believed that the *Streptococcus pyogenes* is the most common infecting agent in severe puerperal infection. In less severe infections, however—e.g., mild localised uterine infections—it does not commonly appear to be the causal organism.

Colebrook and Hare [1] reported that out of 1626 women delivered at Queen Charlotte's Hospital, there were 134 "morbid" and "clinically septic" cases. Of these, only ten (8 per cent.) yielded a culture of *S. pyogenes* from the uterus. In the remainder the predominant organisms recovered from cultures were diphtheroid bacilli, *B. coli*, non-hæmolytic streptococci, and various unclassified Gram-negative organisms. White [2] in Melbourne, out of a series of 25 cases of so-called "sapræmia" bacteriologically examined, reported only one infection due to *S. pyogenes*. Armstrong and Burt-White [3] stated that out of 34 cases of puerperal pyrexia of genital origin this organism was found in only eight instances.

METHOD OF INVESTIGATION.

Eighty-nine cases notified as puerperal infection have been investigated. Every case on admission to the Edinburgh City Hospital had a blood culture and uterine culture taken. Only aerobic cultures were made. Anaerobic organisms are said to play only a very minor part in the production of the disease, and Kinloch, Smith, and Stephen,[4] in their investigations on maternal mortality in Aberdeen, made only aerobic cultures. The uterine culture was made at the bedside. A blood-agar plate was inoculated in the usual way and immediately taken to the laboratory and incubated for 20 hours at 37° C. The plate was then examined for hæmolysis and suitable colonies were selected for further examination. Hæmolytic streptococci were easily identified. The colonies were small, round and dew-drop in size, being more opaque at the centre than the periphery. Hæmolysis was noted by a small circular clear area surrounding each colony. In 27 of the cases investi-

gated further steps were taken, and all types of streptococci were classified according to Holman.[5] Suitable colonies of streptococci were picked off the blood-agar plates, and cultures of peptone water agar containing the sugars lactose, mannite, and salicin were inoculated. This medium was prepared as follows :—

Ordinary peptone water was solidified with 2 per cent. agar, just enough litmus being added to colour the medium a light blue. The sugars (lactose, mannite, and salicin—all 10 per cent. sterile) were then added while the agar was warm. 0·5 c.cm. of 10 per cent. sugar was added to 5 c.cm. of medium and the culture sloped in the usual manner. After solidification had taken place a few drops of sterile human serum were run over the surface of the medium by means of a large platinum loop. After inoculation these cultures were incubated for 48 hours and then examined for fermentation. If fermentation occurred it was invariably always noted first near the bottom of the tube.

CLASSIFICATION OF CASES.

There were 61 cases of localised uterine infection, 9 cases of pelvic inflammation, 3 cases of general peritonitis, 14 cases of septicæmia, 1 case of paratyphoid B complicating the puerperal state, and 1 case of puerperal insanity.

Types of Organisms Cultured from the Uterus in 89 Cases of Notified Puerperal Infection.

Organisms.	Cases.
Hæmolytic streptococci (pure)	24
,, ,, and other organisms	12
Non-hæmolytic streptococci (pure)	19
,, ,, and other organisms	6
B. coli (pure)	2
,, and other organisms	7
Gonococci and other organisms	2
Staphylococcus aureus (pure)	1
,, *albus* (pure)	1
Enterococcus (pure)	1
Unidentified Gram-positive bacilli (pure)	2
Unclassified ,, ,, cocci (pure)	1
Other organisms (mixed)	4
Sterile	5
Contaminated	2

In two cases the uterine culture was accidentally contaminated. Five cultures were sterile. These were taken from cases as follows :—

The first was a case of serum disease. The patient had received antistreptococcal serum 14 days before.

The second was sent into hospital as a "contact" case and suffered from *B. coli* bacilluria.

The third case was not a case of puerperal infection and had no symptoms or fever while in hospital.

The fourth was admitted to hospital on thirtieth day of puerperium suffering from general peritonitis.

The fifth case was one of paratyphoid B complicating the puerperium.

Accordingly the following figures are based on a total of 82 uterine cultures, from which hæmolytic streptococci were obtained in 36 cases (44 per cent.) either in pure culture or in association with other organisms. Hæmolytic streptococci were present in pure culture in 24 cases (29 per cent.). Eleven of these cases were severe septicæmias, all giving a pure growth of hæmolytic streptococci on uterine culture.

In 27 Cases in which the Streptococci were Classified, the types were as follows.

	Uterine culture.	Cases.
Hæmolytic	*S. pyogenes* (pure)	11
	S. anginosus (pure)	1
	S. pyogenes with *Staph. albus*	1
	S. pyogenes with enterococci	1
	S. hæmolyticus III. with enterococci	1
Non-hæmolytic	*S. fæcalis* (pure)	7
	S. salivarius (pure)	2
	S. ignavus (pure)	1
	S. salivarius with diphtheroids	1
	S. non-hæmolyticus I. with *B. coli*	1

Of the 11 cases giving a pure growth of *S. pyogenes*, eight were cases of puerperal septicæmia.

Out of the 89 cases, 11 died. One patient with general peritonitis died. Her blood culture was negative, and the uterine culture gave non-hæmolytic streptococci. The other 10 deaths occurred in septicæmia cases.

EXAMINATION OF CULTURES.

The following results were obtained on examination of the blood cultures and uterine cultures of the 14 cases of septicæmia. In this group there were ten deaths—a mortality of 71·4 per cent. Nine cases had streptococci in the blood—in eight cases hæmolytic streptococci, and in one case non-hæmolytic streptococci. Seven cases with hæmolytic streptococci in the blood stream died and one recovered. The one case with non-hæmolytic streptococci in the blood recovered. There was one case with *B. coli* in the blood which recovered. In four cases the blood was sterile; three of these cases died and one recovered. Clinically all four were cases of septicæmia. Of the three which ended fatally, two gave a pure growth of hæmolytic streptococci from the uterus, and the third gave a pure growth of non-hæmolytic streptococci. The fourth case which recovered gave a pure growth of hæmolytic streptococci on uterine culture. The mortality of the cases in which streptococci were found in the blood stream was 77·7 per cent. Of uterine cultures taken from the 14 cases of septicæmia, 11 were found to give a pure growth of hæmolytic streptococci. The uterine culture was further examined for the causal streptococcus in eight of these cases, and *S. pyogenes* was found in every one. Two cases gave a pure culture of non-hæmolytic streptococci, one being *S. fæcalis*. One case gave a mixed growth of *B. coli* and *S. non-hæmolyticus I.*

CONCLUSIONS.

1. Hæmolytic streptococci are associated with the severe and fatal forms of puerperal infection, in which there is a complete absence of the less virulent organisms which are so closely related to the much milder forms of the disease. 2. The milder forms of puerperal infection are due to a localised uterine infection caused by a variety of organisms, including non-hæmolytic streptococci, *B. coli*, Gram-positive bacilli, and Gram-positive cocci (unclassified). 3. Uterine cultures are useful in forming a diagnosis and in giving a prognosis. 4. The prognosis is serious when *S. pyogenes* is obtained in pure culture from the uterus, as it indicates a virulent and severe infection. 5. The prognosis is fair, but must be guarded when non-hæmolytic streptococci are obtained from the uterus. 6. The prognosis is favourable when a mixed growth of organisms is obtained from the uterus, as their presence is associated with a mild and localised type of disease.

I wish to express my thanks to Dr. W. T. Benson, medical superintendent, Edinburgh City Fever Hospital, for his permission to carry out this study and for his ever-ready help.

CLINICAL AND LABORATORY NOTES

NIRVANOL IN THE TREATMENT OF CHOREA.

By C. F. T. East, M.D. Oxf., F.R.C.P. Lond.,
JUNIOR PHYSICIAN, KING'S COLLEGE HOSPITAL; PHYSICIAN, WOOLWICH MEMORIAL HOSPITAL;
AND
E. R. Cullinan, M.D., M.R.C.P. Lond.,
SENIOR DEMONSTRATOR IN PATHOLOGY, ST. BARTHOLOMEW'S HOSPITAL; ASSISTANT PHYSICIAN, WOOLWICH MEMORIAL HOSPITAL.

THIS paper gives an account of the effects of nirvanol on 15 cases of chorea. In the series the ages range from 6 to 21 years.

The severity of the disease has varied a good deal. Four grades have been arbitrarily represented by the figure 1 for the mildest, to 4 for the most severe. These and other points are set out in the Table.

REVIEW OF THE CASES.

History of Illness.—Thirteen of the 15 patients were suffering from their first attack of chorea. Eleven of these had been ill for less than four weeks. Two had been ill for six months and four months respectively. Thus it will be seen it is in early cases for the most part that the effect of the drug is illustrated.

The Action of Nirvanol.—The patient usually shows a reaction to the drug after a few days. This period, with ordinary dosage, is commonly of nine to eleven days' duration. It may be as short as six or as long as fifteen days. The phenomena of this "reaction" are remarkably variable. The syndrome which has been described as characteristic is said to have three features: (1) fever; (2) a quickened pulse-rate; (3) rash. In our cases this triad only appeared four times. But one or more of the symptoms are usually seen. For instance, in three patients the rash was present alone, in one fever and quickened pulse came without the rash, and once there was quickening of the pulse, and the rash appeared without fever. The temperature may rise to 102° F. The heart may accelerate to 120 or 140 beats a minute.

(1) No. of case.
(2) Sex.
(3) Age.
(4) Severity.
(5) Weight.
(6) Amount of drug (in grammes).
(7) Time before reaction (in days).
(8) Rash.
(9) Fever.
(10) Quickened pulse-rate.
(11) Increase in chorea before reaction.
(12) Drowsiness.
(13) Onset of improvement in days since drug started.

15	M.	7	1	3 2	1·1	11	0	0	0	0	0	0

gl. = gradual.

The *rash* is a morbiliform eruption. It is not unlike that caused sometimes by sanocrysin. It does not always appear first in the same places. We have noticed it first on the trunk, chiefly the front, spreading to the face and limbs and back. The maculæ are reddish, bright at first, and then more dusky. Later they coalesce to a brilliant sheet of intense colour which is most pronounced on the extensor surfaces of the limbs. The buccal mucosa may be flushed and show tiny dewy vesicles. Irritation is not troublesome. Desquamation does not occur. The eruption usually begins to fade on the third day. The "reaction" lasts from three to four days.

Increase in the symptoms of chorea, which is sometimes seen, may be disturbing for two or three days before the "reaction." It may even occur when no reaction takes place.

Drowsiness was notable in six cases. In two it amounted practically to coma. On its appearance the drug was stopped and the symptoms of the disease cleared up. Three patients were drowsy and showed no further reaction.

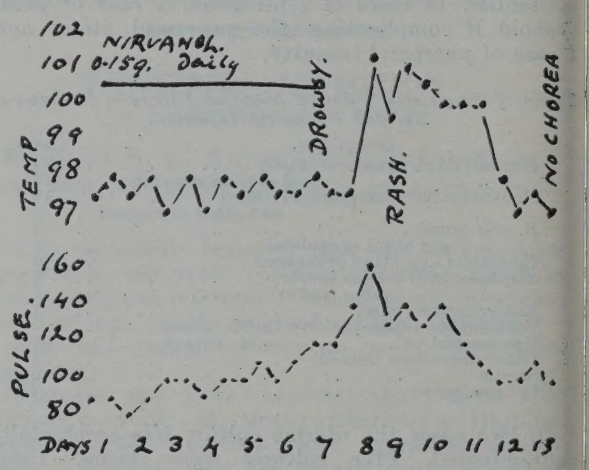

Chart showing effect of nirvanol in Case 5.

Improvement is usual, and took place 8 to 14 days after starting the treatment. It follows the reaction at once, though the reaction is not necessary to the improvement. Five did well without showing a rash. The symptoms cleared up quickly in three cases. The two patients who did not improve showed no response to the drug of any sort.

Dosage.—The drug was given by mouth twice daily. In three cases only was a daily dosage of 0·3 g. exceeded. To two of these 0·4 g. was given daily, and to one 0·5 g. The largest total amount given was 7·2 g., and the smallest 0·9 g. The drug was administered over periods varying from 6 to 15 days. A reaction, when it occurred, was a signal to stop the drug.

Unusual Effects.—In two cases a fall in pulse-rate was the only obvious form of response. In one patient 2:1 heart-block appeared for one day during the exhibition of the drug. It is worth noting that two patients developed rheumatic fever shortly after the nirvanol reaction.

Cardiac lesions were present in six of our cases and did not appear to be in any way affected.

Positive results.—Of the 15 cases, 12 were greatly improved, 1 moderately, and 2 did not respond.

CONCLUSIONS.

It is not possible to foresee what reaction the drug is going to produce. The symptoms of this reaction

may not be dangerous, but they are certainly at times disturbing.

The symptoms of chorea are improved and the attack is cut short in quite a dramatic manner in many instances. The question is whether it is right to use a drug which can produce so variable and uncertain a reaction to treat a disease which is said to be self-limited. The main justification would rest upon demonstration that the abolition of chorea prevented the onset of carditis. This still remains to be proved. We do not know that the rheumatic infection is abolished, in fact two of our cases point to the opposite.

For these reasons we think that the use of nirvanol should be restricted to cases which show no signs of improvement after four or five weeks' treatment on ordinary lines. It should only be used when constant supervision is available.

A CASE OF THROMBO-ANGIITIS OBLITERANS.

BY G. NORMAN CLARK, M.B. ABERD.,

HOUSE SURGEON, HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL.

A MAN, aged 40, was admitted to the Hampstead General Hospital on March 6th, 1930, complaining of pain and swelling of his right leg.

ACCOUNT OF THE ILLNESS.

He had experienced pain on the outer side of the calf on sudden movement for the last seven years. In October, 1929, he had had similar pains on walking, and after being in bed an hour or so his foot had become numb. This numb feeling had been relieved by hanging the leg out of bed. A month later there was constant pain in the foot, which was pink and swollen. On account of the swelling and pain he had remained in bed from the middle of December until the end of January, but there had been no improvement in his symptoms. Since then the pain, redness, and swelling had been getting worse. His previous health had been quite good. He was not a drinker but smoked between 25 and 30 cigarettes a day. He had been a keen hockey player since the age of 16 and had been goalkeeper at football for the last 15 years. He could not trace any Jewish ancestry.

He was a well-nourished healthy-looking man. There was marked swelling of the right foot and leg with redness of the toes and the distal part of the foot. The swelling pitted on pressure and on elevation of the limb the redness faded away, the limb becoming quite blanched. There was a discharging area on the plantar aspect of the little toe which had been incised three weeks previously, a misdiagnosis of sepsis having been made. The outer aspect of the little toe was painful and tender and there was an indurated tender area with redness of the skin on the inner aspect of the right calf. Below the inner tuberosity of the tibia there was a patch of phlebitis of the long saphenous vein which was painful and very tender. Pulsation could not be made out in any of the arteries of the legs distal to the femorals in Scarpa's triangle. The right pulse at the radial was weaker than the left, which could be felt readily. No pulsation could be felt in the antecubital fossæ. The blood Wassermann and Meinicke reactions were negative and a radiogram of the leg showed no evidence of calcification of the arteries. The heart sounds were weak but no murmurs were heard. His blood pressure was 115 mm. systolic and 75 mm. diastolic.

The pain was very severe while in hospital, being relieved by hanging the leg out at the side of the bed; even nepenthe ℥x. at night did not relieve it with any certainty. Ultra-violet light was tried locally, with temporary relief of the symptoms.

On March 31st the swelling was more marked, and extended up beyond the middle of the leg, and the pain was so severe and constant that the patient wished to have his leg amputated. Injection of the short saphenous and plantar nerve to the outer side of the little toe with 0·5 c.cm. and 0·25 c.cm. of absolute alcohol respectively gave him temporary relief from the pain in the little toe.

Amputation above the knee was done on April 8th by the long anterior and short posterior flap method. The wound healed well and the patient had an uneventful convalescence except for occasional "phantom pains." He was discharged on April 30th.

The arteries of the amputated limb and the short saphenous nerve at the point of injection were dissected out; likewise the thrombosed segment of the long saphenous vein below the internal tuberosity of the tibia. There was considerable difficulty in dissecting out the vein, which was bound down to the surrounding tissues.

PATHOLOGICAL REPORT.

Dr. C. R. Lane reported on the condition as follows:

The popliteal artery is occluded by a thrombus one inch below the line of amputation; above this there is no thrombus. At the point where it is occluded the adventitia is thickened and tends to merge into the surrounding tissues; the vasa vasorum show a little endarteritis and periarteritis, but these are far from being marked; where they do occur, increase in elastic tissues is marked. The media shows intense degeneration of the muscle, especially internally, being replaced, not by fibrous tissue, but by elastic tissue apparently derived from the elastic fibres of its innermost layers. Its vasa vasorum are dilated. The internal elastic lamina is reduplicated and markedly fragmented in places. The intima is merged into the thrombus, which is completely organised and consists of fibrous tissue, in places hyaline, with many small vessels showing endothelial and muscular coats with little or no elastic tissue. Nearest the internal elastic lamina the thrombus shows an enormous amount of elastic tissue, apparently derived from the internal elastic lamina. In the centre are cells bearing altered blood pigment.

In the region where the popliteal artery is patent there is some endarteritis, again with much elastic tissue and reduplication of the internal elastic lamina. There is degeneration of the media, especially internally, with a good deal of elastic tissue, but also some loose fibrous tissue; the adventitia is well defined. The vasa vasorum do not show endarteritis. The popliteal vein shows endophlebitis, mainly due to increase in elastic tissue in the subendothelial region. It is patent but shows commencing thrombus formation.

The anterior tibial artery shows marked canalisation of the thrombus and rather more endarteritis of the adventitial vasa vasorum, but otherwise a similar great increase and reduplication of elastic tissue. There is endophlebitis of the venæ comites. The dorsalis pedis artery is not blocked, but there is marked narrowing of the lumen by increase of the subendothelial tissue, largely by elastic tissue. The media is fairly well preserved. There is increase of the elastic tissue of the adventitia. Endarteritis of the vasa vasorum is not marked. The posterior tibial artery and its branches are not blocked; they show similar changes to the dorsalis pedis artery but with less elastic tissue. Endarteritis of the vasa vasorum is more marked. The internal plantar artery is similar to the dorsalis pedis. The external plantar artery is also similar to the dorsalis pedis, but the subendothelial tissue shows extensive canalisation. One vein is also in a similar condition, but the subendothelial tissue is more fibrous and has very little elastic tissue. The long saphenous vein contains an extensively canalised organised thrombus showing much elastic tissue; there is considerable diffuse round-celled infiltration round the vasa vasorum. The short saphenous nerve shows considerable fibrosis with destruction of nerve-fibres.

Apparently the condition was an affection primarily of the elastic tissue and intima, the effects on the media being secondary. Great increase of elastic tissue is not usually described in thrombo-angiitis obliterans, but the more advanced stage seen in the popliteal artery is the usual finding in that disease.

I wish to thank Mr. W. H. Ogilvie, who had charge of the case, for his kind permission to record it, and Dr. Lane for permission to publish his report on the microscopic findings.

SMOKING IN HOSPITAL WARDS.—In future male patients in Bath Royal United Hospital are to be allowed to smoke in the wards between 7 and 8 A.M., 1 and 2 P.M., and 6 and 7 P.M. The resident medical staff are, however, empowered to prohibit smoking when it appears likely to be prejudicial to the health of any patient.

REVIEWS AND NOTICES OF BOOKS

Epidemic Encephalitis.

ETIOLOGY, EPIDEMIOLOGY, TREATMENT. Report of a Survey by the Matheson Commission. New York: Columbia University Press. Pp. 849. 15*s*.

WE know from Sir Thomas Browne that "some allow that such diseases which are esteemed new will have but their time." Neurologists are already beginning to apply this dictum to epidemic encephalitis as they mark a progressive diminution in hospital and clinic of cases of the disease. Yet it is too early to look upon epidemic encephalitis purely as medical history; 1037 cases of the disease were notified in England and Wales during the year 1929. Whether or no epidemic encephalitis is to become a tale that is told it is of paramount importance to collect all available data about its manifestations. Mr. William J. Matheson decided to have the information scattered in journals or monographs in every language brought together and tabulated so as to be generally available. With his financial support and at his instance a Commission was appointed to represent the laboratory, clinical and epidemiological points of view. The actual detailed work was done by Dr. Josephine B. Neal, who analysed the 428 pages of the bibliographical section of the report, and also visited England and the continent of Europe in order to confer personally with the chief workers on epidemic encephalitis. The result of the Commission's labours is this book, which, illustrated by many statistical tables, charts, and diagrams, has assembled in succinct form the known facts relating to the manifestation of epidemic encephalitis throughout the world.

For the most part the Commission have desired to put evidence before the reader without drawing any very definite conclusions. This is particularly to be remarked in the epidemiological section. The examples of epidemic outbreaks and of apparent case-to-case infection are cited side by side with instances of outbreaks in which no such association is manifest. Reference might have been made to the views which harmonise these apparent discrepancies by adducing data relating to mild and abortive cases of epidemic encephalitis and the possibility of "carriers" of the virus. On the analogy of two other epidemic diseases of the central nervous system —cerebro-spinal meningitis and acute poliomyelitis— it seems likely that epidemic encephalitis is infective and liable to manifestation in epidemic form. A chapter is devoted to other types of encephalitis, including post-vaccinal encephalitis. More information is certainly required not only about the pathology and symptomatology of the forms of encephalitis which follow on acute infectious diseases, notably measles and small-pox, but also (as the work of W. R. Brain and others indicates) about the sporadic and epidemic forms of encephalitis which now occur with greater frequency in our midst. The problem of the ætiology of post-vaccinal encephalitis is still unsolved. Some consider it possible that vaccination produces diminished resistance to disease and that an organism of encephalitis, already present without causing any symptoms, becomes pathogenic; others believe that the condition is due to the introduction of a neurotropic virus with vaccine lymph.

We are glad to note that the Matheson Commission is continuing its work on epidemic encephalitis and that the results of further studies of the causes, treatment, and sequelæ of the disease will be published from time to time.

Diseases of Women.

Fourth edition. By Ten Teachers under the direction of COMYNS BERKELEY. Edited by COMYNS BERKELEY, H. RUSSELL ANDREWS, and J. S. FAIRBAIRN. London: Edward Arnold and Co. 1930. Pp. 558. 18*s*.

AMONGST the text-books commonly used by medical students, Diseases of Women and its companion volume Midwifery by Ten Teachers rank second to none in popularity. Collective authorship necessarily involves compromise over debatable points and this in turn usually means that the product lacks those dogmatic statements which are essential in all elementary teaching. In this book, however, the student will have no difficulty on this score although in later life he may find that he has to revise some of his ideas. To get representatives of nine London schools to agree to a uniform teaching is a triumph, and even a greater one when agreement can be maintained over a term of years. In this edition the whole book has been completely revised, and recent work has been incorporated in the text. The authors have restricted the additions as far as possible to established facts and have avoided theories and contradictory statements. This treatment of new work may seem unsatisfactory to the specialist, but it greatly simplifies the subject for the average student for whom the book is written. The treatment of carcinoma of the cervix is not very clearly described. Technical details are given of both operative and radiological methods, but the student is left without any guidance about the relative positions these two lines of treatment hold in this and other countries. A great reduction in the weight of the book has been brought about by the use of lighter paper.

The student will find no better text-book to help him through his examinations, and in later life he will find it an equally valuable friend in practice.

Introduction to Human Parasitology.

By ASA C. CHANDLER, M.S., Ph.D., Professor of Biology, Rice Institute, Houston, Texas. New York: John Wiley and Sons; London: Chapman and Hall, Ltd. 1930. Pp. 655. 25*s*.

THIS book is an elaboration of one entitled "Animal Parasites and Human Diseases" by the same author written 12 years ago. It is pleasant to see recorded the assistance he has obtained in the interim from the *Tropical Diseases Bulletin* among other journals. Prof. Chandler has produced a sincere and readable book, not overburdened with tiresome details on human parasitology. Throughout the work special emphasis has been laid upon the biological aspects of the subject, and considerable space has been devoted to life-cycles, epidemiological factors, and underlying principles of treatment and prevention. The introductory chapters on parasites are good and we may note that in the controversial subject of nomenclature no attempt has been made to give a synonym, but, whenever there has been disagreement between European and American usage the latter has always been adopted. Prof. Chandler is patriotic enough even to countenance the inclusion of *Councilmania* as a well-established genus of amœba parasite in man; some may regard him as uncritical for including bronchial spirochætosis as a distinct

entity, attributed to a specific organism, *Treponema bronchiale*. The illustrations are a little disappointing, both in number and in quality. Fig. 287 is a caricature of *Aedes calopus* (sic), the yellow fever mosquito, which is quite out of proportion. Why should it be named *calopus* on one page and *aegypti* on the next?

We have recently had occasion to welcome standard works on modern protozoology, medical entomology, and helminthology in the English language. The production of a comprehensive work on human parasitology is timely, and this volume gives clearly and with good judgment all the information which readers will seek to find in its pages.

Psychology, Normal and Abnormal.

By J. W. BRIDGES, Professor of Psychology in the Faculty of Medicine of McGill University. London: D. Appleton and Co. 1930. Pp. 532. 12*s*. 6*d*.

THIS is one of the most comprehensive text-books of psychology that has appeared for some time past. In a brief opening chapter the author defines psychology from various aspects, and relates it very ably to the related sciences of biology, the normative sciences, other mental sciences, and the pseudo sciences (spiritism, &c.). He then defines the relation of normal to abnormal states in a succinct manner, and discusses the philosophic foundation of the subject. The neurological substratum or correlates of mental activity and behaviour are considered at some length and a systematic study on orthodox lines is made of functions. The relationship of functions to applied psychology and psychopathology are critically examined. The references to psycho-pathology throughout the book are considerable though necessarily brief.

Students of medicine who are not to be satisfied with oddments of psychology will find the book interesting and informative.

Treatment in General Practice.

By HARRY BECKMAN, M.D., Professor of Pharmacology at Marquette University, Milwaulkee, Wisc. London: W. B. Saunders Company. 1930. Pp. 899. 45*s*.

DURING the past 15 years applied physiology has steadily come into its own by the orderly filling up of the breach between medicine and physiology, but therapeutics has been largely excluded from this happy union. Medical men have, in consequence, fallen back according to their individual temperaments either upon therapeutic nihilism or, contrariwise, upon the easily assimilable brochures provided by enthusiastic theorists or industrious manufacturers. Dr. Beckman in this outstanding book steers a course from which both these points of view are excluded. Being both pharmacologist and physician, he is in a position to do so. And yet, great as has been and is the need for the literature of applied pharmacology, this book is more than that. It is a most painstaking and exhaustive analysis of orthodox and putative therapeutics in medicine (surgery and midwifery are not included), written critically and giving details of technique and dosage. In the preface Dr. Beckman decries the current principle that the art of treatment "comes" if only one has mastered the art of diagnosis, and the book is an attempt to shake, however feebly, the false foundations of such beliefs. Yet nowhere in the book will it be found that the treatments discussed are independent of diagnosis properly made. This tribute should not be taken to imply that students will find here any rule-of-thumb index of treatment. Far from it: the book is one written by a tutor and not by a "coach." Two full pages, for instance, on the successful treatment of diabetes mellitus by myrtillin will certainly not be found to be lightly transferable to a daily prescription sheet, and the section on asthma will probably leave the average doctor wiser chiefly by his increased recognition of the darkness surrounding the subject. But, nevertheless, many refreshing passages should help him to increase the efficiency of his armamentarium in the treatment of hæmoptysis, syphilis, chronic nephritis, herpes zoster, eczema, and a host of other diseases when diagnosis has been established.

This book or its equivalent should be in the hands of every physician, and we have not yet come across its equivalent.

Radiographie néphro-cholécystique.

By M. DE ABREU, del'Institut Brésilien de Sciences et de L'Académie de Médecine de Rio. Paris: Masson et Cie. Pp. 157. Fr.40.

THIS monograph contains only 23 pages of text, the rest of a considerable book being devoted to illustrative cases and a short résumé. The author has evolved an original technique for the differential diagnosis of renal and biliary stones, and other intra-abdominal shadows; he does not discuss the numerous methods already employed. In most cases this differential diagnosis is not a difficult one, but it must be admitted that there are cases which give rise to doubt. In these the author suggests that a profile view, with the X ray beam passing through the plane of the kidney from the pelvis to the posterior border will completely separate the shadows of the kidney (and any stones it may contain) from the shadow of the gall-bladder. This picture is, of course, through the maximum diameter of the kidney, and therefore should give a renal shadow of maximum density. The profile view of the kidney is obtained by rotating the patient on the couch to an angle of approximately 45 degrees, and the author claims that this position also frees the kidney shadow from that of the psoas muscle and air shadows in the bowel. The value of serial radiograms at 10 degrees of rotation is pointed out. Some 54 illustrative cases are included which are well reproduced, and help to support the author's contentions.

The book should prove of interest to all radiologists interested in urological diagnosis.

Procedure in Examination of the Lungs.

By ARTHUR F. KRAETZER, M.D., Chief, Medical Department, New York Skin and Cancer Hospital. London: Humphrey Milford, Oxford University Press. 1930. Pp. 125. 8*s*. 6*d*.

THIS book is written as a practical manual for students. The author wisely insists on the importance of understanding the normal before trying to study physical signs in disease, and the student is told how to examine a normal chest and compare one area with another. The different signs and symptoms are then described, and the reader is warned to be methodical and not to take one striking sign, base a diagnosis on it, and build up other signs of doubtful

value to suit the diagnosis. Dr. Kraetzer considers the coin sound a detestable sign. A student given a case of pneumothorax may "get a fool hunch right at the start and look for the coin sound," thus avoiding the routine examination that should have led to the diagnosis. When dealing with tuberculosis the author gives much commonsense advice. The presence of serous effusion means tuberculosis, "unless you can disprove it, and the odds are a hundred to one you cannot."

The book is written in a very light and almost conversational style, but contains many valuable hints on the interpretation of signs and symptoms of pulmonary disease.

Elektrotherapie.

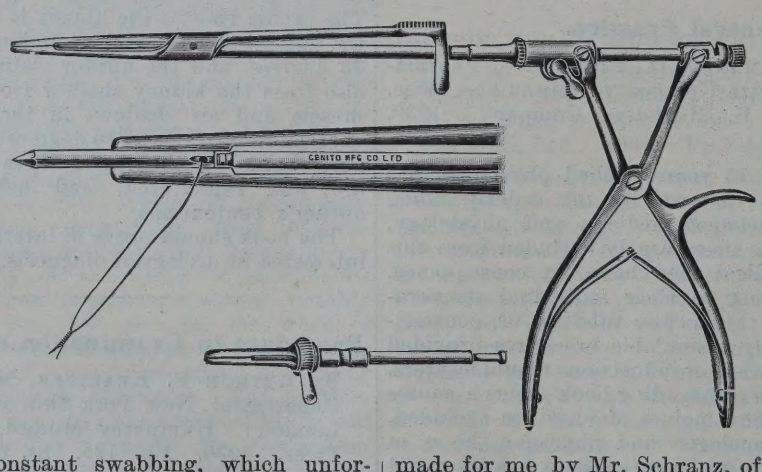
Third edition. By Dr. JOSEF KOWARSCHIK, Head of the Institute of Physical Therapeutics of the State Hospital, Vienna. Berlin: Julius Springer. Pp. 312. M.22.60.

THE second edition of this book was written six years ago. The present edition contains less electrotechnical detail, and the space thus saved has been utilised for the addition of the more recent advances in electrical treatment. The size of the book remains the same. The new material includes a brief account of the chronaxie and its possible uses in electrodiagnosis. In the section on diseases of the alimentary system there is a short description of the use of diathermy in some of the diseases of the gall-bladder; this form of treatment is recommended in cases of chronic inflammation, especially where there is painful spasm, and when adhesions are present. In the pages devoted to treatment of diseases of the skin the author describes the use of diathermy in place of the galvanic current for destroying superfluous hair follicles; and he comments favourably on the work of others in the treatment of keloid, X ray ulcers, and acrodermatitis atrophicans by diathermy. In selecting the diseases for which electrical methods of treatment can be recommended and in describing the results which may be anticipated, Dr. Kowarschik speaks with praiseworthy restraint. He might well have written more about electrical methods in diseases of women. Only four pages are devoted to this subject, and these are placed at the end of the section on diseases of the urogenital system. This short account is quite inadequate in view of the importance of the subject. A new expression, not familiar to English readers, is used for the treatment introduced by the late Prof. Bergonié. Just as the words "Franklinisation" and "d'Arsonvalisation" were introduced to describe certain forms of treatment by static electricity and by high-frequency currents, the expression "Bergonisation" has been coined to signify the treatment in which the muscles of the limbs and trunk are made synchronously to contract and do work. These are long words, but they serve to keep in memory the work of three very distinguished pioneers.

NEW INVENTIONS

A RADIUM NEEDLE INTRODUCER.

WHEN radium needles are being placed around and into malignant growths, much time can be saved and the work much simplified if each needle can be introduced and fully embedded in one act. The usual procedure is, of course, to enter the needle as far as the needle-holder permits and then to embed it by means of a special "pusher."



The object of the instrument here depicted is to do this in one instead of two movements. I designed it primarily for use with bladder and prostatic carcinoma; in these cases the work has to be done at the bottom of a cavity where visibility can only be obtained by constant swabbing, which unfortunately often dislodges the needles and yet is necessary if the pusher is to be fitted on to the needle. This instrument can, however, be used for implanting any needles into any growth to which direct access is possible. Needles of various thickness and length are easily put into the jaws of one or other of the holders, all of which fit on to the same handle. When using the instrument, the needle held in it is driven into the tissue by pushing, and then, whilst a firm pressure is maintained, the handle is closed, and thus the needle is propelled for the last part of its course and buried entirely beneath the growth's surface. In dealing with very dense tissues it is particularly important to maintain a very firm pressure whilst pushing, and thus to ensure that the point of the instrument is kept in close contact with the surface of the growth or skin overlying it.

The principle on which the instrument works can be seen from the detailed drawing; the pushing rod ends in a truncated cone which, on closing the handles, enters and slightly opens the jaws holding the needle and in the same movement forces it forwards.

The instrument has been carefully made for me by Mr. Schranz, of the Genito-Urinary Company. It consists of a handle and three extensions for work at various depths and adapted for various lengths of needles. There is also one very short extension for superficial work; only this latter and one longer are figured.

R. OGIER WARD, M.Ch. Oxf., F.R.C.S. Eng.,
Assistant Surgeon, St. Peter's Hospital; Surgeon in Charge, Genito-Urinary Department, Miller General Hospital.

THE LANCET.

LONDON: SATURDAY, JULY 26, 1930.

ANÆSTHETICS IN CHILDBIRTH.

THE appeals in the lay press for funds in order that every woman in hospital who desires it may have an anæsthetic to dull the pains of childbirth have stimulated public imagination, and expressions of medical opinion on this subject are being sought especially from obstetricians, anæsthetists, and general practitioners. In the current number of the *British Journal of Anæsthesia* a leading article is devoted to the question whether our maternity service would be improved by the provision of anæsthetics. The point of view adopted is that the present lack of such provision is mainly a financial question, but is also due to a "dormant obstetric conscience." Many women do not ask for an anæsthetic because they have no idea that labour pains can be alleviated without damage to themselves or to their child. As a matter of fact, quite apart from the humanitarian aspect of the question, the use of anæsthetics in labour has definite obstetric advantages. The memory of unrelieved pain in a first labour causes in many women grave apprehension of the coming ordeal in subsequent pregnancies—a quite unnecessary additional strain which does not conduce to the welfare of either mother or child. Again, if pain is duly relieved, and the patient's condition during labour gives no other cause for anxiety, doctors and relatives are likely to agree to let delivery be spontaneous, whereas if the woman is distressed it is common for the patient's friends to beg the doctor to force the pace by forceps delivery. The most marked advantage noticeable at the end of a labour which has been made painless is the absence of shock or exhaustion.

But if such relief from the pains of childbirth is to be given, certain safeguards are necessary. It is obvious that when the patient is under the influence of a drug and can make no complaint, more, and not less, systematic skilled obstetric observation is required if the progress of normal labour is to be distinguished from one in which difficulty is arising. A careful watch must be kept on the character of the pains and on the progress made; signs of exhaustion in the mother or of adverse effect on the child must be looked for, and this demands a skilled attendant with much time at his disposal and much patience. A real risk connected with the use of anæsthesia in labour assumed to be normal may arise from a desire to leave the mother's rest undisturbed, thus allowing danger signals to pass unnoticed. No difficulty occurs with those patients who can afford a long period of vigilant care from both accoucheur and anæsthetist; nor should it arise in maternity hospitals where sufficient personnel is available. There are, indeed, good reasons for hoping that the public will find generous support for the funds designed to enable anæsthetics to be given in lying-in hospitals. First, there is the fact that here, at least, one can provide relief of pain without increasing the danger; secondly, the medical student and midwife learning their jobs on anæsthetised patients are likely to retain the sympathetic outlook with which they enter hospital, and will not steel themselves deliberately to disregard cries and expressions of agony as inevitable accompaniments of the process of childbirth; thirdly, research will be stimulated, so that relief which is now feasible only inside the hospital walls will eventually be provided for women confined at home. How this blessing could be achieved will remain a problem at least until the present range of anæsthetics has been more thoroughly explored with this end in view, and probably until the range has been extended. The suggestion has been made that anæsthetists might themselves discuss the possibility or desirability of training in anæsthetics a certain number of midwives who are also fully qualified nurses. It is acknowledged that nurses have been successfully employed as anæsthetists in the United States, even for operations involving full surgical anæsthesia, but the best medical opinion in this country has always been opposed to the admission of anyone but a qualified doctor to the ranks of those allowed to give anæsthetics for any purpose whatsoever. It is obvious that the doctor who conducts a forceps case without the help of a colleague must entrust the administration of anæsthesia to the nurse, but he is in the room and in an emergency can, and often does, leave his obstetric operations to attend to the mask—sometimes to have to return to them without washing up. A very great improvement in the general education of the nurse-midwife would be required before the authorities could be asked seriously to discuss her training as an anæsthetist, and this possible solution must be dismissed as impracticable with the anæsthetics at present on the market.

There remains the hope that some new methods of analgesia in labour may be discovered. In our present issue Mr. J. S. M. CONNELL reports on his experience of the use of avertin in some 50 cases. He does not claim that the drug ensures a painless labour, but that by its use "it is possible to make things so easy for the patient that she has no devastating pain, no prolonged backache, no exhaustion, and no memory of a terrible experience to jaundice her outlook on life." Admittedly the drug has drawbacks and dangers, and Mr. CONNELL suggests only that it is worthy of trial by the practitioner. If this is so, it is also worthy of inclusion among the drugs being tested by Mr.

ALECK BOURNE and Dr. J. H. BURN for their action on the human uterus.[1] A simple apparatus for recording graphically the changes in the uterine pressure taking place during labour has enabled them to show the effect on the behaviour of the uterus of chloroform, ether, nitrous oxide, stovaine, morphine, atropine, and quinine. Their conclusions are that: (*a*) The administration of chloroform or ether on an open mask at once arrests the contractions in the first stage, and diminishes their force and frequency in the second stage. The effect comes on rapidly, and passes off rapidly when the administration is discontinued. (*b*) The administration of gas and oxygen has no effect on the contractions during labour. (*c*) Stovaine (intraspinal) does not inhibit the contractions, but interferes with full relaxation between the pains. This appears to be due to continuous contraction of the lower segment, and if stovaine be given early in the first stage dilatation will be delayed. (*d*) Morphine lessens the frequency of uterine contractions, but the pains pass off more slowly, so that the work done by the uterus is probably as great as or greater than before, despite the lessened frequency. (*e*) Atropine appears to stimulate the contractions of the uterus. It certainly has no inhibitory action. (*f*) The stimulant action of quinine during labour is very small. The most important of these conclusions from the point of view of those who are eager to secure painless labour for women in lying-in hospitals is that which acquits gas and oxygen of any deleterious effect on the contractions of the uterus. The apparatus is cumbersome, the administration requires experience and skill, and the depth of anæsthesia attainable may not suffice to make the actual delivery painless. But the very fact that one form of anæsthesia has been proved to cause no delay in parturition will encourage the search for others equally harmless which can be more easily administered. The pioneer work of Mr. BOURNE and Dr. BURN has initiated a new and valuable method of approach.

SURGICAL BIOGRAPHY.

THERE has just been published an alphabetical series of biographies of the Fellows of the Royal College of Surgeons of England covering the period from the institution of the order of Fellows in 1843 down to 1922, when VICTOR PLARR, their author, died after a short illness. PLARR, it will be remembered, was librarian of the College for over 30 years and these important volumes[2] form a fitting testimonial to his industry as well as to his literary capacity. That there should be published by the College a biographical record of its Fellows was proposed originally in 1912 by Sir JOHN BLAND-SUTTON, and again when he became President of the College, knowing that PLARR had already started on the work. The obituary notices which had appeared in THE LANCET were, in the initial stage, PLARR'S inspiration, as he frankly said, while at that time the question of money precluded the College from publication, although PLARR continued to add to his notes. But recently the Council of the College, under LORD MOYNIHAN'S Presidency, invited Mr. D'ARCY POWER, Mr. W. G. SPENCER, and Prof. GASK, who had been members of the Library Committee of the College, to revise and prepare PLARR'S M.S. for printing and publication, since when other sources of information have been drawn upon. The cost of issue has been defrayed from a legacy of £5000 made to the College by the late Mr. THELWALL THOMAS, and the volumes for this reason bear the name of that well-known surgeon and generous man.

The lives of the Fellows form a valuable record of the progress of surgery at the hands of its best known exponents during the past 90 years: the appellation "best known" can be justified on the law of averages, and does not suggest that the Fellows of the other Royal Colleges have not produced corresponding leaders of their art, many of whom incidentally fall for mention in the English series. By the publication of these biographies the period of some 90 years of surgical history is bridged over, and largely by the solid construction of contemporary recollection, for here we find set down many things known personally, and few things that have not been received by their retailers at first or second hand. This position has, of course, its drawbacks as well as its advantages, for it is thus inevitable that the note of the work should be one of eulogy. How could it be otherwise when the main source of information has been the biographies published in the medical press during the week of the demise, while in many instances relatives, perhaps quite near relatives, of the dead man will still be living? In certain instanees the monotonous note of appreciation detracts from the value of the compilation, omissions made from delicacy marring the accuracy of the record, but it is good to know that these reservations are not to be deplored in the case of anyone who really counts in the history of his science. The disregard for proportion in the length of the obituaries would, again, be an easy matter to criticise, but much interesting reading is due to this very absence of symmetry, for some of the longer obituaries owe their length not so much to the eminent professional position of their subjects as to the accident of association with some notable circumstances outside the profession.

It is intended to issue supplementary volumes every ten years, and it will be advisable that these should contain revisions as well as additions. It will be of real use to the writers of medical history if those who have access to information which would enable some of the more meagre entries to be supplemented would communicate with the Librarian of the College, and would clothe certain skeletons with their appropriate tissues. The period over which retrospection has to extend is so brief that it seems probable that there lies to hand much of the necessary information.

[2] Thelwall Thomas Memorial: Plarr's Lives of the Fellows of the Royal College of Surgeons of England. Bristol: John Wright and Sons; London: Simpkin Marshall, Ltd. 1930. Two vols., pp. 752 and 596. Price, 42*s*. cloth; 57*s*. 6*d*. half bound.

A GENERAL MEDICAL SERVICE.

THE possibility of a State medical service with its attendant bureaucratic control has begun to haunt the medical profession of recent years. Whether or not this spectral presence has moved the British Medical Association directly to draw up a scheme for a general medical service, it has certainly had a definite and material influence in the matter; for it is with the sentiment that offence is the truest defence that some constructive proposals have come from the Council of the Association. If the State should extend the scope of clinics and centres, and further absorb the work still carried on by the general practitioner, it is clearly desirable that the medical profession should be able to offer some basis for a scheme in accordance with its own views and traditions, things which State organisation might disregard.

The details of any such scheme will necessarily call for close scrutiny and wide discussion before actual trial, while modification after the scheme has been put into practice—if ever—may be needed; but the Representative Meeting of the Association indicated accurately the possible reactions of the general practitioner to certain of the Council's proposals, and in so doing has also informed the public of much that matters. The position of the medical officer of health in the scheme was the subject of much debate. The proposal of the Council that he should act as liaison officer between the local general practitioner and the local authority was challenged by Dr. E. R. FOTHERGILL, on the grounds that it was possible that not all medical officers of health were in perfect accord with the general practitioners in their district. This is an old story, and, as far as we know, it has received no new support from actual events, but Dr. H. J. MILBANK-SMITH advocated the formation of a statutory medical committee for the area to consult with the medical officers of health on matters affecting the local practitioners. The proposal to form such a committee was inspired by the feeling that the M.O.H. would probably meet the local authorities only three or four times in the year, and yet would be in a position to make decisions affecting the welfare of local practitioners in which they could have no dissentient voice. The opposite point of view was put very ably by Dr. J. MIDDLETON MARTIN, who felt the interests of the profession to be a concern which the medical officer of health would have at heart; he spoke feelingly of the difficulties of administration cumbered by too many opinions, and rather gave the impression that medical officers of health were guardian angels brooding over the welfare of practitioners in their area. Dr. D. O. TWINING's conception of them was rather different and he classified them either as Mussolinis or mice; but, like Dr. FOTHERGILL, he felt disinclined to confide the welfare of the general practitioner to either group. The meeting agreed that the local medical advisory committee should have direct access to the local authority without the intervention of these third parties.

In his introductory speech Dr. BONE made it clear that the financial aspect had been purposely excluded from the proposals, but it was felt that these would be incomplete without some tentative reference to the probable cost of the scheme. In a separate section of the proposals this has been attempted in figures on a basis of calculations made by the Royal Commission on National Health Insurance of 1926, and the following figures are quoted from that reference: the cost of extension of the present National Health Insurance Scheme to dependents of insured persons (£9,500,000); a consultant and specialist service for present insured persons (£1,290,000); laboratory aids for present insured persons (£100,000); making a total of £10,890,000. The British Medical Association's estimate of the cost of its Maternity Scheme was approximately £2,250,000. Against these figures are certain "set-offs," notably the whole cost of the present additional treatment benefits given under the National Health Insurance. The amount spent in this way in 1928-29 in England alone was £3,622,869. As Dr. J. W. E. CORY pointed out at the meeting these figures are by now somewhat out of date and their deletion from the proposals was considered. It was felt, however, that in being asked to discuss any scheme of this kind the public should be given some idea of the cost even if it could not be assessed with complete accuracy, and the meeting decided to retain these paragraphs as they stood.

The proposals as a whole make a basis for a complete scheme which, considering its extent, should not prove unduly costly if the financial estimates are at all sound. The London Public Medical Service, now in action in Kensington and Paddington, forms an interesting practical experiment of the application of such a scheme on a small scale. Part of a motion containing a reference to it was ruled out of order by the chair in the position in which it was introduced, but some further reference will doubtless be made to it in the course of the meeting. The Council's proposals cover a wide field and make provision for all classes of patients, including the indigent. Only experiment can prove the value of the scheme as a practical measure.

THE OSLER CLUB.—The Osler Club celebrated on Saturday, July 12th, the eighty-first anniversary of the birthday of Sir William Osler. Prof. Harvey Cushing, having been welcomed as a "Friend of the Club," gave an informal oration in which the charm and whimsicality of Osler's personality was well brought out. He told of the early Western days, of Father Johnson and of James Bovell, and of how, under their influence, Osler turned from the church to medicine. He also let his audience into the method employed in writing his great life of his friend and master. Dr. Arnold Klebs, Sir Arthur Keith, Sir D'Arcy Power, Dr. Henry Wellcome, and Mr. Philip Franklin then entered on a lively discussion of Osler as physician, author, and man, until Mr. W. R. Bett remembered that it was "long past Osler's bedtime," and wound up the proceedings with a tribute to the influence of Cushing's "Life of Osler" upon the later generations of medical men. Before the oration the club entertained Prof. Cushing to dinner at the Langham Hotel.

ANNOTATIONS

THE TRAFFIC IN DANGEROUS DRUGS.

THE tenth assembly of the League of Nations last year approved the principle of limiting the manufacture of dangerous drugs as foreshadowed in The Hague Convention of 1912. The council of the League, last May, at its fifty-ninth session, approved a plan which is to be submitted to an international conference to be held next December. Meanwhile the recent issue of a report for the year 1929 by the British Government shows how by the Dangerous Drugs Acts 1920–25 illicit traffic has been brought under control in this country. While seizures of contraband have been relatively few and far between in Great Britain, reports from the Dominions and Colonies and from several foreign countries afford disquieting evidence of widespread illicit traffic abroad. International coöperation, as contemplated by The Hague and Geneva Opium Conventions, has not been effective, and indeed some important countries have not even troubled to reply to letters addressed to them. Nevertheless, it is satisfactory to learn that the exports of British-made morphine and its salts, which some years ago amounted to tons, last year totalled 42,331 ounces, a decrease of 7492 ounces on the previous year. The consignment to France was nearly 5000 ounces less than in 1928. Three-fourths of the raw opium imported for medicinal purposes now comes from India and only about one-fourth from Turkey, while Persian opium has practically ceased to be employed. The report states that "as prepared opium (i.e., opium for smoking) is totally prohibited in Great Britain, all quantities seized are destroyed" and "active police measures are taken to detect infringements of the law." Such commendable vigilance here contrasts with the continued exports from India of "prepared opium" for smoking purposes, yielding a not inconsiderable revenue to the Government. In 1928 cocaine was for the first time manufactured under licence in this country, and in 1929, 9326 ounces were so manufactured against 4934 ounces in the previous year, the imports of the alkaloid showing a corresponding decline.

It would be well if all the high contracting parties to The Hague and Geneva Opium Conventions would furnish as precise and satisfactory reports as that just issued by the British Government. Official statements from the League of Nations, however, bear witness to the widespread and dangerous extent of the illicit traffic in opium, morphine, heroin, and cocaine, as well as to the ingenuity and resource of the organisation for this clandestine commerce. The advisory committee on opium at Geneva, which has been labouring for the last ten years, is to have an infusion of new membership, while the Permanent Central Opium Board has, in the five sessions it has held, found it difficult to compile statistics of illicit traffic owing to the failure of producing countries to furnish complete returns. No machinery which can be contrived to grapple with this complex problem will be effective unless and until the nations, which have solemnly pledged themselves to effectuate treaties, enact and enforce the legislation which such treaties imply.

HEALTHY SLEEP.

IT is an ancient jest about the disagreement of doctors that their advice on the best position in which to sleep is so positive, and at the same time so various, that the only thing to do is to remain stark, staring, wide awake. This is no libel, for in actual fact three American doctors have found in the literature vigorous reasoned advice against sleeping in every possible position. Some postures are said to produce deformities and other to correct them, and every posture in turn is accused of interfering with the action of the heart, stomach, or respiration.[1] The United States army urges its soldiers never to forget that "the best way to use the body for all purposes is as if it were stretched up as tall as possible"; during sleep they are not to "curl up and buckle" in the middle. Yet other authorities recommend a curled-up position, and this at least seems more reasonable, since the "position of rest" for all parts of the body is one of flexion, following the rule that the flexor muscles are slightly more powerful than the extensor.

Where such differences exist it is obvious that someone has based an opinion on inadequate evidence. It is easy enough for the physician to notice that two or three patients with a certain disease state that they always sleep in a certain position, but to give the position an ætiological importance on these grounds is unjustified. There are two fallacies: one is the lack of adequate control experiment and the insufficiency of numbers, and the other is the fact that the patient's statement is worth very little without the corroboration of an observer. The American workers, during the course of an investigation into sleep conducted at the Mellon Institute, Pittsburg, have invented an ingenious device to record the movements of healthy people in bed. A pen is attached to a part of the bed which yields to the sleeper's movements when he changes the position of a limb or of the body. The pen writes on a strip of moving paper, which also records the passage of time, and each jag in the line represents a movement. A study of 112 healthy people and 70 patients in hospital, and in addition of some children and university men, has shown that the average healthy sleeper changes his position between 20 and 45 times in a typical night of eight hours, and holds about half the positions he takes up for less that five minutes. He does not lie still for an hour at a time once in the night. "Log-like" slumber was only produced by heavy doses of opiates. An extension of the recording device included a cinematograph camera which automatically took the position of the sleeper each time he stirred and ceased to stir. The paper is illustrated with 33 sketches showing the corresponding number of different positions taken up by a typical sleeper, together with a clock showing the times at which he moves. If the bed is comfortable for all positions the sleeper turns through about a dozen gross positions with minor variations in a fairly regular sequence throughout the night. Those that are maintained for fairly long periods are invariably contorted; the spine is always curved laterally and usually bowed backwards and twisted. Even when he lies on his back he does not lie flat, but places one leg in such a way

[1] Johnson, H. M., Swan, T. H., and Weigand, G. E.: Jour. Amer. Med. Soc. Assoc., 1930, xciv., 2058.

as to prevent rotation and throw more of the weight on to the other side. The posture that requires least effort to maintain is a prone one.

The conclusion is that any healthy sleeper would have to be strapped in a frame or moulded in a cast if he were to spend the entire night in the position recommended by any one physician; on the other hand, he contrives to please all of them at some time or another. Just as the best diet for a healthy person is to eat what he likes, so the best posture for healthy sleep is a series of changes as dictated by nature. No one of the positions adopted gives the "complete relaxation" shown in a fainting person, but each relieves the irritation and corrects the errors of the previous position and of the day's activities.

TRANSMISSION OF MATERNAL IMMUNITY.

CHICKENS in the egg and new-born rabbits have very little power of producing antibodies in response to stimulation by a foreign antigen, and it may be assumed that the fœtus in utero is in at least as disadvantageous a position. In man and other animals (monkeys and rodents), in which the placenta is permeable to antibodies, the young one comes into the world already charged with the products of its mother's antibody responses, and is in a good state to resist the attacks of microbes which immediately are made upon it. New-born babies give a negative Schick test—i.e., have diphtheria antitoxin in their blood—about as frequently as adults; about three-quarters of them are protected against diphtheria. As time goes on this dose of maternal antitoxin wears off, and at a year old only about one-quarter of the children will be found Schick negative, and they have to set to work to learn to produce their own antitoxin as they come in personal contact with the diphtheria bacillus. The protection of new-born children against diphtheria or tetanus would be more complete than it is if their mothers were immunised with toxoid during pregnancy, which would not be an unreasonable thing to do. But in other animals, and notably in ruminants, the placenta is thicker and does not allow antibodies to pass from mother to fœtus; the young reach the world entirely without protection, and this may have most disastrous results, as in the "lamb dysentery," which sometimes kills a third of the produce of a flock. Theobald Smith showed some time ago that calves reached the world in this unprotected state and that if they were denied all access to their mother were very likely to perish from a general infection with *Bacillus coli* from their intestines. He found further that they were protected if they sucked their mothers' milk, or if they were given by hand a dose of her colostrum or indeed a dose of her blood. Maternal immunity in the cow is, therefore, transmitted through the colostrum and not across the placenta. The brilliant work of Mr. T. Dalling and his co-workers at the Wellcome Laboratories at Beckenham, the latest phase of which is described in the current number of the *Journal of Pathology and Bacteriology* (vol. xxxiii., p. 783), shows that the same holds for the sheep. Lamb dysentery, as they have shown, is due to a bacillus closely allied to, but apparently not identical with, Welch's bacillus of gas gangrene. It may be prevented by dosing each lamb as it is born with the appropriate antitoxin from an immunised horse, but as may be imagined this is not a convenient or even a practicable thing to do under the conditions which prevail at lambing time in the north of England and south of Scotland, where the disease is particularly prevalent. Equally good results are obtained more easily by immunising the ewes with toxin-antitoxin mixtures at leisure during pregnancy. It is now shown conclusively that the maternal antitoxin passes to the lamb via the colostrum, in which antitoxin reaches a higher concentration than in the ewe's blood for a few days after delivery. It is well-known that antitoxin given by the mouth is ordinarily useless, and that it is destroyed in the processes of digestion. But this, remarkably enough, does not apply to the lamb for about the first three days of its life; during that time horse antitoxin given by the mouth is absorbed and can be demonstrated in the blood; from about the fourth day onwards the alimentary tract is impermeable. Other experiments show that the new-born puppy and foal have the same convenient capacity of absorbing antitoxin given by mouth; the new-born baby seems to have it only to a trivial degree. The whole is an excellent illustration of the predominance of ends over means in determining the behaviour of animals. One way or another all species reach the same end, and the new-born young is furnished with maternal antibodies; animals with thin placentas put it in during pregnancy, those with thick placentas through the colostrum immediately after birth.

THE VITALITY OF ENAMEL.

ABOUT two years ago Sprawson and Bury[1] reported that analyses of human enamel revealed a constant though small amount of organic matter. The delicate methods employed made it certain that enamel is not entirely inorganic and the earlier work of Sir Charles Tomes was thus confirmed. Whether enamel is a vital tissue which can undergo constructive change after eruption is a question much debated. One school holds that it is within the pale of nutrition and thus subject to metabolism in the same way as bone. The other denies the possibility of any alteration after it has once been formed. Most of the evidence for and against these views has been based on histological and staining appearances, but clearly the first necessity was for analysis by methods chemically beyond reproach. Hence the significance of Sprawson and Bury's observations, and Mr. Sprawson has now followed them up by studying the microscopic structure of marsupial and human enamel.[2] He finds that enamel can readily be penetrated by stains from the pulp cavity; the stain does not extend through the whole thickness of the enamel but for a distance depending largely on the age of the tooth. Since the stain can only reach the enamel via the dentinal tubes, which are definitely known to contain protoplasm, it seems a reasonable inference that its passage into enamel depends also on spaces which are not artefacts but part of the normal structure, and, like the spaces in dentine, filled during life with lymph. The tubes in marsupial enamel lie between the enamel prisms, as previously shown by Mummery and von Ebner. Sprawson finds that the patency of the tubes varies with age and that they are more permeable in young animals. As age advances the enamel becomes more highly calcified, by deposition of calcium salts in the interprismatic spaces. This reaction implies nutritional processes in the enamel, since only in this way could the density of the tissue increase. Similar staining reactions

[1] Sprawson, E., and Bury, F. W.: Proc. Roy. Soc., B., 1928 cii., 419; see THE LANCET, 1928, ii., 610.

[2] Proc. Roy. Soc., B., 1930, cvi.

have been noted by others, but under conditions which did not entirely preclude the penetration of stain through cracks artificially produced. But the regularity of the phenomena now described by Sprawson and the large number of teeth examined seem to leave little doubt that enamel is a vital tissue in which an exchange of calcium salts takes place. He shows incidentally that cracks in the enamel are common and are probably due to the trauma of mastication. When these cracks occur the enamel and dentine in the vicinity react; the dentine tubes and the interprismatic spaces in the enamel first enlarge and then become hypercalcified. Thus a crack which is at first a definite solution of continuity may be so completely healed as to leave only a linear scar.

Although Mr. Sprawson's paper is primarily a study of marsupial enamel, he reproduces five sections which leave little doubt that the observations apply also to human enamel. He marshalls his arguments with exemplary caution, and the illustrative photomicrographs are beautiful.

VEGETARIANISM AND BLOOD PRESSURE.

THE relation between dietetic habits and raised blood pressure is not likely to be a simple one of cause and effect, though excess of food of animal origin, and especially of meat, is often held to favour hyperpiesis. Enough records seem to have been made of men who, on the one hand, have eaten a great deal of such foods without developing any rise in blood pressure and, on the other hand, of men who have high blood pressures in spite of abstemiousness in this respect, to make it certain that other factors play a determining part. It might still be true, nevertheless, that meat-eating in conjunction with other factors makes a person relatively liable to increased blood pressure, and this is the thesis suggested by Dr. Felix Saile [1] as the result of a series of observations carried out during the past two years. He chose for his subject 110 monks belonging to the Trappist, Carmelite, and Carthusian orders, whose rules forbid the use of meat, fish, eggs, and butter, and as controls he employed 115 monks from the Dominican and Franciscan orders, who are permitted to eat meat four and five times a week respectively. The mean blood pressure of the vegetarians was considerably lower than that of the controls at all ages from 20 to 90. The difference was greatest in the age-group 60 to 70, where the mean for the vegetarians was 120 mm. Hg, and for the meat eaters 160 mm. Hg. Interesting as such observations are, they cannot be considered conclusive, a fact which is recognised by Saile himself. The general rules of life differ widely in the two sets of orders. The Trappists, Carmelites, and Carthusians are under a vow of silence, and live secluded lives devoted largely to manual work, or to study and contemplation, as the case may be. The Benedictines and Franciscans, on the other hand, come into closer contact with one another and with the outside world, and live what ordinary folk would consider a much more normal life. It remains yet to be proved, therefore, that the diet of the two groups of orders was the primary factor determining the difference in the average height of their blood pressure.

TUBERCLE BACILLI IN THE BLOOD.

THE final positive diagnosis of tuberculosis rests almost entirely upon bacteriological evidence, and accordingly it has become the practice to examine any or all of the excretions in the hopes of finding the organism. According to R. Russew,[1] examination of the blood itself with this object was first carried out successfully by Villemin, and since his original observation it has been generally accepted that bacilli can be recovered in cases of severe miliary tubercle. In the type of disease for which Landouzy coined the word "typhobacillose" it is likewise supposed that tubercle bacilli are swarming in the blood stream, but here the infection is too massive and virulent to permit of tubercle formation and a true bacillæmia leads to death. The conception of tubercle bacilli in the blood in these acute cases is readily acceptable, and of greater interest are Russew's results in much less acute cases and in so-called surgical tuberculosis. The method he employs is that devised by Prof. Löwenstein, in whose clinic in Vienna the work has been done, and it is to strict attention to detail that he attributes his success. Tubercle bacilli were discovered in the blood of six out of seventeen patients with pulmonary tuberculosis and some of the positive results were cases where the temperature was normal or subfebrile. The association of bacillæmia with a good general state is strikingly demonstrated in the cases of surgical tuberculosis. Here, in a group of eight patients, six had tubercle bacilli in the blood and yet were free from fever and in a good general state of health. Russew's work suggests that tubercle bacilli are recoverable from the blood more often than is generally recognised and that this bacillæmia does not necessarily mean a fatal prognosis. If surgical tuberculosis is accompanied by bacillæmia the possible excretion of tubercle bacilli by such patients has to be considered, and this has an important bearing on their infectivity. Another deduction would be that in cases of long-continued pyrexia of unknown origin a blood culture should be done by Löwenstein's method.

HYPOGLYCÆMIA AND SUPRARENAL TUMOUR.

CLINICIANS are now familiar with the distinctive train of symptoms which is provoked by an overdose of insulin. The analogy offered by other endocrine glands suggested the possible existence of a condition of spontaneous hypoglycæmia and led to the discovery of the rare condition now known as hyperinsulinism, the pathological basis of which is hyperplasia of the islet cells of the pancreas. Hypoglycæmia of lesser degree has been observed in other conditions such as Addison's disease and acute necrosis of the liver. Again, the hunger, intense muscular weakness, and tremor which often follow prolonged muscular exercise in a fasting subject, are symptoms suggestive of hypoglycæmia and are quickly relieved by sugar. Certain cases of adiposity associated with excessive craving for sweet food are also capable of the same explanation.

H. B. Anderson[2] records a case of hypoglycæmia associated with a tumour of the suprarenal body.

The patient was a man of 33, admitted to hospital in a state of coma, from which he could with difficulty be roused. He was very restless and perspired freely.

After intravenous injection of 60 grammes of glucose he quickly regained consciousness. On leaving hospital he remained well except for attacks of uncontrollable temper.

[1] Wien. Archiv f. Inn. Med., 1930, xx., 231.
[2] Amer. Jour. Med. Sci., July, 1930, p. 71.

Later he was readmitted in coma and could not be revived by glucose. His blood-sugar varied between 0·04 per cent. and 0·08 per cent. Post mortem an encapsulated tumour, apparently a cortical carcinoma, replaced the left suprarenal and the right suprarenal was smaller than usual. The pancreas was normal, apart from some vascular congestion towards the tail.

It is clear that hypoglycæmia played a large part in causing the symptoms in this case. Hypoglycæmia is not surprising in a lesion of the suprarenal capsule in view of the opposite effects exerted on the blood-sugar by insulin and adrenalin. It cannot, however, explain the patient's death, for although it was recognised early intravenous injection of glucose failed to save the patient. Evidently some more important factor, probably destruction of the cortical suprarenal tissue, which is known to be essential to life, was concerned.

CYCLICAL VOMITING.

BIOCHEMICAL research has thrown much light on periodic attacks of sickness in childhood, and the associated "acidosis" has been widely studied. The condition is fairly well defined. The attacks may begin early, usually in nervous children, and sometimes recur with remarkable regularity, the child being apparently well in the intervals. The onset may be sudden, but is often preceded by a day or two's malaise, irritability, and, commonly, constipation; during this time acetone bodies may be detected in the urine. Vomiting is at first severe; it may persist for hours or days, and be associated with profound collapse, but recovery is rapid, and death in an attack is almost unknown. Many attempts have been made to account for the periodic nature of the disorder, and the good health of the patients between the attacks. Some observers regard the vomiting as a form of childish biliousness, allied to the "bilious attacks" or migraine of adults, and there is no doubt that such children not infrequently develop typical migraine in later life, while a hereditary factor unquestionably plays a part in both conditions. Others look on cyclical vomiting as merely a general reaction to a simple gastro-intestinal "upset"; but although dietetic errors and constipation can often be found before an attack, it is hard to believe that these can be wholly responsible. A third body of opinion regards the condition as an allergic reaction, comparable in ætiology to asthma and hay-fever, and due to protein sensitisation; whilst some look upon it as a form of juvenile "hysteria." The view most widely held, however, is that the condition is essentially metabolic in origin, and there is much to support this theory. The constant presence of ketone bodies in the urine points to disordered metabolism both of fat and carbohydrate. The ketosis may be intense, and is almost always associated with some degree of hypoglycæmia. During an attack the blood-sugar has been found as low as 37 mg. per cent., and amounts of oxybutyric acid as high as 5 g. a day have been noted in the urine. Often there is a greatly increased excretion of urea, and sometimes there are large numbers of casts, comparable to those found in the acidosis of diabetic coma. Little exact information is available about the condition of blood apart from its sugar content, but no marked changes have been found in the reaction, or in the percentage of creatinine or fat. There are also few reports on the frequency of intestinal intoxication, and the output of such substances as indican in the urine during the attacks. A reduction of blood-sugar appears, however, to be almost constant, and H. C. Cameron and others have been led from this to lay much emphasis on the hypoglycæmia of the "nervous child." It is clearly important, therefore, to determine if possible how far the subject of cyclical vomiting is abnormal between attacks, and in his response to stimuli that may be expected to call them forth. Among these stimuli may be mentioned dietetic errors—especially an excess of fat or sudden limitation of carbohydrate—severe physical exertion, and emotional influences. L. Salomonsen, of Oslo, reports [1] that he has examined a number of normal children with this object, and his results are interesting. In 15 healthy infants between 1 and 4 years old, subjected to complete starvation for 48 hours, the blood-sugar fell to between 31 and 70 mg. per cent., whilst the blood acetone and blood fatty acid values rose considerably; in 9 a large number of casts appeared in the urine. In 12 healthy children, aged 5 to 14 years, a sudden change to an excess of fat in the diet led to symptoms closely resembling those of cyclical vomiting, but of very variable intensity, which reached a maximum after two to five days of the high fat diet. Chance febrile attacks during such "alimentary acidosis" in healthy children greatly increased the ketonuria. Six children who suffered from cyclical vomiting showed no difference, in response to precisely similar changes in diet, from those seen in the normal children. There was thus no indication that such children are in any metabolic respect different from healthy children, and Salomonsen concludes that there is no evidence that cyclical vomiting is a "metabolic disorder." It is, he thinks, an entirely physiological response, exactly analogous to what can be artificially produced in healthy children by sudden restriction of carbohydrate. The precise cause which leads to the onset of an attack he leaves undecided.

USE OF THE LEFT HAND.

A hundred and fifty years ago Benjamin Franklin published "The Petition of the Left Hand," urging the use of that neglected member to aid and relieve its fellow. Since then we have learnt a great deal about the treatment of left-handed children, who are no longer scolded into neurosis for using the hand which comes natural to them. The majority who are right-handed, however, seldom do anything to encourage the use of the left hand, and in the French Academy of Medicine on July 8th Dr. Armaingaud appealed for a wider recognition of the value of ambi-dexterity.[2] The experience of men who lost their right hands in war service has shown how successfully the left hand can be trained, and the advantage of being able to use either hand as occasion demands is obvious. Dr. Armaingaud mentioned the value of ambidexterity to surgeons, and senior members of the Ophthalmological Society will recall the way in which Critchett could remove the lens of the right eye with the right hand and the lens of the left eye with the left hand at a single operation. Dr. Armaingaud frankly characterised right-handedness as an "invalidité artificielle," and he so far impressed the members of the Academy that the subject was referred to a committee for consideration.

WE regret to announce the death at Torquay, in his eighty-eighth year, of Dr. Thomas Outterson Wood, well known in connexion with psychiatric work. We hope to publish an account of his long and valuable career.

MODERN TECHNIQUE IN TREATMENT

A Series of Special Articles, contributed by invitation.

CCCIII.

THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS.*

PART I.

PULMONARY tuberculosis, as seen in the adult, is rarely a primary infection; it is a reinfection. The body has already acquired a degree of immunity which means that the organisms find themselves in an environment, in a measure prepared to resist them. In those cases in which the primary invasion has produced but a low grade of immunity, and, at the reinfection, large quantities of tubercle bacilli are disseminated in the lungs, there is rapid spread of the disease, which is extremely difficult or impossible to control. On the other hand, the resistance may be completely effective, or it may be partially so only, and, as a result, one finds in the lung caseation, fibrosis, and cavitation. Here we are chiefly concerned with :—

(*a*) The cases in which the resistance of the individual, even when fostered and assisted by sanatorium treatment and hygiene directed to the improvement of the general health, fails to prove efficient. This may be because the tubercle bacilli have had too long a start, or because their relative potency to the resistance is too strong, or the individual's resistance is not overcoming the tubercle bacilli sufficiently fast, the time factor being of importance.

(*b*) The cases of chronic or fibroid phthisis, in which the pathological fibroid tissue which has formed, while beneficial in checking the too rapid advance of the tubercle bacilli, becomes in turn detrimental to the lungs. This fibroid tissue is continually shrinking and so diminishing the volume of the lung. Some compensation is possible by the falling in of the chest wall, the displacement of the mediastinum, and the compensatory emphysema of the healthier parts of the lungs. This, however, does not prevent the deleterious influence of the fibrosis on the bronchi and bronchioles, which gradually become dilated and hypertrophied, so that a condition of secondary bronchiectasis with retention of secretions and toxæmia develops.

(*c*) Cases with cavities too large, or with walls too well defined to heal under medical treatment. These cavities, in addition to being responsible for continued toxæmia, are dangerous as potential sources of severe hæmoptysis.

(*d*) Cases of serious, long and continued or recurring hæmorrhages, whether they come in the previous category or not.

Surgery, in the treatment of pulmonary tuberculosis, is not the performance of a radical operation producing a cure, and needing but the healing of the wound and convalescence. It is an adjunct to medical treatment, aimed to overcome those obstacles which are causing sanatorium treatment alone to fail, and designed to readjust the anatomical, physiological and pathological intrathoracic balance, so that sanatorium treatment can play its part without an overwhelming antagonistic handicap.

The objects of surgery are to rest the lung, to remove the tension and distortion strain of the pathological fibrous tissue formation, to abolish abnormal cavities whether in the lung parenchyma, due to dilatation of the bronchi, or in the pleural cavity; finally, to prevent the recurrence of hæmorrhages. All these objects are obtained by one means only—the collapse of the lung; it is the manner of procuring this collapse that differs according to the circumstances of the case.

* The substance of this article was communicated to the Congress of the Royal Institute of Public Health held in Portsmouth in June, 1930. Part II. will appear next week.

The surgical methods available for obtaining these ends are artificial pneumothorax, oleothorax, phrenic evulsion, extrapleural pneumolysis, thoracoplasty, and multiple neurectomy. Some of these collapse, to a great or less extent, the whole lung, others are entirely or mainly local in their action.

Artificial Pneumothorax.

The lung is separated from the chest wall by the pleural sac in which there is normally a negative pressure equal to about 6 mm. of Hg. If this pleural sac is filled with air until the intra- and extra-pleural pressures are both at atmospheric pressure or zero the normal lung will collapse completely by virtue of its elasticity. This is the result aimed at when an artificial pneumothorax is done for disease. Its realisation, however, often fails. One reason for failure is that a lung extensively fibrosed, or with thick walled cavities, or containing areas of consolidation is incapable of such complete collapse, even if the intrapleural pressure is raised above zero. An excessively mobile mediastinum may be another cause for failure in that, even before the intrapleural pressure is zero the mediastinum becomes displaced to the opposite side and, pressing on that lung, embarrasses its ventilation and the oxygenation of the blood. This can sometimes be checked by the introduction of gomenol oil. A far more frequent and serious difficulty in the production of a successful pneumothorax is the presence of adhesions between the two layers of the pleural membranes. These, holding out the lung, prevent a collapse sufficient to be of any value in 40 per cent. of the cases attempted, and interfere with complete or reasonably complete collapse in 20 per cent.

Artificial pneumothorax, when it produces complete or almost complete collapse of the lung, either without the necessity of dividing adhesions or after the division of these, is one of the most successful methods of treatment for pulmonary tuberculosis. In most of these cases the benefit becomes almost immediately apparent by the reduction in temperature, the improvement in the pulse-rate, the diminution of cough and sputum, and the lessening of dyspnœa. The reduction in the toxæmia is responsible for great benefit in the general condition and a gain in weight. In the very earliest stages there is often increase of cough and sputum and loss of weight, but these are temporary only.

The results of Matson, Matson and Bisaillon in 600 cases were as follows :—

—	Cases	Clinically well.	Arrested.	Dead.
		Per cent.		
Satisfactory compression	235	48·5	18·7	22·0
Partial compression	245	11·4	11·8	58·0
No free pleural space	120	5·8	9·2	66·6

CONTRA-INDICATIONS.

The contra-indications to artificial pneumothorax treatment, apart from failing heart, nephritis and extensive tuberculous enteritis, are based on the anatomical extent of the disease in the opposite lung. If there is only slight root involvement, not interfering too greatly with air entry, or a localised lesion of a lobe, it is justifiable to attempt a complete pneumothorax on the more affected side. If the better lung

has, however, more extensive disease than that just indicated, it is wiser to aim at a partial pneumothorax. Under these circumstances it is particularly advantageous if a "selective collapse" can be obtained—i.e., collapse more or less localised to that area chiefly affected by disease. In certain cases with simultaneous bilateral active disease it may be necessary to establish a bilateral pneumothorax, that on the less involved side being started as soon as the first is satisfactorily established. Bilateral pneumothorax is also done in cases in which, the one lung being under control, the disease later spreads in the other. In either case the pneumothorax is, of course, partial only, and great care is required so to control the total collapse that too great a strain is not placed on the heart.

It may be as well here to emphasise once again the importance of the correlation of sanatorium with surgical treatment. In the initial stages of pneumothorax rest in bed is essential. Until the temperature has settled down, until the pulse-rate has steadied and the patient's general condition has improved, exercise is strongly contra-indicated. Further, constant X ray control is essential. There is the danger of excessive mediastinal displacement and of hernia of the pleura; there is the still greater danger of tearing open thin-walled cavities when partially held out by adhesions; there is the frequent complication of pleural effusions which necessitate alterations in the routine of the refills of gas; there are the difficulties associated with the lung that refuses to stay collapsed, and creeping out despite refills, becomes progressively adherent.

ADHESIONS.

The serious import of adhesions is clearly shown by the results. With a complete pneumothorax 48·5 per cent. of the patients heal and can return to and carry on with their work; but with a pneumothorax in which the collapse is interfered with in whole or in part by adhesions, only 9·3 per cent. are so restored to health. The finest adhesions will often rupture, especially during a fit of coughing when the intrapleural pressure is considerably raised. Moderately fine adhesions will stretch, and may in time yield sufficiently to allow efficient collapse of the lung. It is the broader string-bands and the veils which are the trouble. Some of these contain vessels of considerable relative size; others are fibrous in their peripheral part only, whilst the central part consist of a cone-shaped, drawn out part of the lung. It is obvious, therefore, that the division of these, unless special precautions are taken, is accompanied by the risk of hæmorrhage from the vessels or of the escape of blood and air from the divided part of the lung, and later of infection also.

The invention of the thoracoscope which enables one to see in the pleural cavity led naturally to the thermocautery for the division of these bands. The latest advance has been the use of diathermy, which coagulates the adhesion and diminishes still further the risk of hæmorrhage from the vessels when dividing the adhesion. Hitherto the thoracoscope has been introduced through one cannula and the cautery through another. Quite recently F. G. Chandler has brought out a thoracoscope of small calibre which combines the means for applying a diathermy current and of cauterising the adhesion. It is a most ingenious and practical instrument, and enables one to tackle with confidence quite large adhesions and broad bands.

COMPLICATIONS.

The commonest of all the complications of artificial pneumothorax is pleural effusion. It is said to occur sooner or later in from 30 to 50 per cent. of all cases. It may be transient, being rapidly absorbed, and in such cases it is usually beneficial, as it may lead to a less rapid absorption of the gas. More often an effusion, once it has started, tends to become chronic. The effusion may be sterile or loaded with tubercle bacilli. At first the effusion is clear, with a small cellular content; after repeated aspiration it becomes richer in cells and fibrin, to such a degree at times that it is very difficult to aspirate. The onset of an effusion is generally associated with increase of pyrexia, and sometimes interference with the fluid leads to greater rises of temperature. An effusion may on the one hand cause increase of intrapleural pressure which is deleterious; on the other hand, it may cause the lung to become adherent and to re-expand. In long-standing cases there is always the danger of secondary infection. An effusion causing symptoms of distress from too high a positive pressure must be aspirated and replaced with air; it is unwise, however, to remove the whole of the liquid. If the liquid contains tubercle bacilli, it may be possible in the earlier, more acute stages to sterilise it by injecting methylene-blue in absolute alcohol. Later the effusion should be replaced with olive oil and gomenol. If the effusion is persistent despite these methods of treatment thoracoplasty may be indicated.

Oleothorax.

The use of oil in the pleural cavity has been practised now sufficiently long to permit of a certain amount of dogmatism as to its indications and its value. The oil used is either olive oil or paraffin, to which has been added 0·5 to 5 per cent. of oil of gomenol. Oleothorax is not an alternative to pneumothorax, though on occasion it may be used as a substitute. An oleothorax must never be attempted in a virgin pleural cavity on account of the reaction likely to be produced. The value of gomenol oil is due to its disinfectant action, to the changes it produces in the pleural membranes, making them more rigid and impermeable, and, on occasion, to its compressing action on the lung. One of the most important indications of gomenol oil is in the treatment of pyo- or pyo-pneumothorax, whether occurring as a complication of artificial pneumothorax or from other causes, when either the pleura is infected with tubercle bacilli alone, or in the treatment of a mixed infection. In these cases also the oil must not be used until the acute stage of the lesion has subsided. In cases of pyopneumothorax complicated by bronchial fistula oleothorax may be successful in obliterating the fistula and clearing up the infection in the cavity. In cases of pneumothorax with hernia of the pleura or with a mobile mediastinum, gomenol oil will prevent the recurrence of the former by causing thickening of the pleural membranes; for the same reason it will cause fixation of the mediastinum. An oleothorax may lead to greater compression of the lung than can be obtained by a pneumothorax; it may also retard the obliteration of a pneumothorax when the lung is becoming progressively adherent. Lastly, in certain cases of artificial pneumothorax, for which the frequent refills of air are difficult to arrange, gomenol oil may be substituted for the air. The thickening of the pleura and the slow rate of absorption enable the intervals between the refills to be prolonged from every two weeks or so to about two months. Olive oil is absorbed more rapidly than paraffin, and is, for this reason, more generally used in the treatment of effusions. When an oleothorax is done to replace a pneumothorax so as to

extend the interval between the refills paraffin gives the better results. The great precaution necessary with either olive oil or paraffin-gomenol is to test the reaction of the pleural membranes to it. A big initial dose may produce an alarming reaction. For this reason 5 or 10 c.cm. should be the maximum amount injected at the start. This can be increased to 30 or 50 c.cm. at the next injection, while subsequent doses can be doubled or trebled according to the absence of pyrexial response.

The simplest method of injecting gomenol oil is by means of a Jubet blood transfusion syringe or with a 30 c.cm. syringe. A short needle should be used with a bore of 1 mm. The oil must be warm. When treating an effusion this must be aspirated before the oil is run in.

Medical Superintendent, Vale of Clwyd Sanatorium
Consulting Surgeon, University College Hospital.

SPECIAL ARTICLES

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING IN LONDON.

PROCEEDINGS OF THE REPRESENTATIVE BODY.

THE annual Representative Meeting of the British Medical Association opened at Tavistock-square on July 18th, with Dr. C. O. HAWTHORNE in the chair. Dr. W. G. WILLOUGHBY, medical officer of health for Eastbourne, was elected President of the Association for 1931–32.

Expansion of National Health Insurance.

On behalf of the Council, Dr. H. G. DAIN moved a resolution stating that the time is now ripe for the medical profession to ask that the dependents of insured persons should be included under the national health insurance scheme. The attitude of the public towards their medical service was, he said, steadily changing; there was an increasing tendency to consider that medical attention was necessary for minor ailments. While it was desirable that an efficient medical service should be available for everyone, its maintenance must become increasingly costly; the general practitioner stood between the devil of encroachments by the public health centres and clinics, and the deep sea of a whole-time medical service which might suddenly engulf him. It was futile to try to forbid development along one or other of these lines. Under the new Local Government Act local authorities had acquired a wide control of hospitals and certain domiciliary services. Extension of the present service of clinics and welfare centres of various kinds could be made gradually without any sudden outlay, but the inclusion of dependents in the national health insurance scheme would mean the immediate provision of a large sum of money. Left in the hands of the local authorities the clinics would gradually gather in this class of patient completely, leaving the medical profession no say in the matter. In some parts of London a well-patronised public medical service run on a contributory basis afforded an objection to a compulsory insurance scheme, but this appealed only to the thrifty type of patient and was not accepted generally. The time had come for practitioners to choose between an insurance system with a free choice of methods, and a whole time medical service with control by the local authorities.

An amendment to this motion, introduced by Dr. E. WARD (Torquay), to provide that the capitation rate for such dependents should be not less than that paid at present for insured persons was lost, on the ground that it limited any demands for remuneration to that sum. But an interpolated plea from Dr. DAIN that policy should not be mixed with business, and that the financial question should be postponed until later, provoked a robust protest from Mr. E. B. TURNER (Kensington). It had been his happy lot, he said, to avoid panel practice, but observation had led him to the conclusion that it was ludicrously underpaid. This was the fault of the medical profession for accepting the system without first demanding a sound financial basis, and unless remuneration were discussed before Dr. Dain's motion was carried, the same result would occur in this case. Any scheme involving the care of women and children would entail an enormous increase of domiciliary work, and if the service were not to be disgruntled adequate payment was an essential. Mr. Turner threw in a frank reflection on the origin of the fees: obviously they could not come from the employer, or the man of many children would be permanently out of work; the insured person himself was unlikely to be in a position to pay; in fact the scheme meant another sixpence on the income tax, so there was every reason why the capitation rate should be adequate.

Dr. J. S. MANSON (Warrington) proposed an amendment, which was carried, to the effect that the extended service should include adequate safeguards respecting remuneration and terms of service. Dr. DAIN then put the motion in the amended form; it was, however, opposed by Dr. PETER MACDONALD (York), who said that his constituents considered that in their district the community was already fairly well served, that in the event of inclusion of dependents in the scheme the economic condition of the doctor would be worse and the work increased to breaking strain, and that they deprecated any step that would reduce private practice. Dr. H. M. STRATFORD (North Kensington) spoke of the London Public Medical Service, now in action at Paddington and North Kensington, which, he said, was successful enough to make any additional scheme appear unnecessary to practitioners who belonged to it. Dr. H. B. BRACKENBURY recalled to the meeting the major premiss of Dr. Dain's argument. It was not possible to ensure that the present state of affairs would continue. To pass the motion was the only way to avoid the danger of a whole-time medical service, which would undoubtedly be adopted in the course of the next few years unless some alternative plan were offered.

Dr. DAIN, in summing up, said that in many industrial areas there was no private practice among dependents of insured persons; this large body of patients attended clinics and hospitals. Only by their proposed inclusion in the national health insurance scheme could they be brought under the care of the general practitioner. The amended motion was then carried.

Hospitals and Private Practice.

The Council has this year provided a revised hospital policy based on a reconsideration of the entire scheme. The classification of patients has now been made under three headings, free, contributing, and private, thus avoiding the term "tariff patient," which never received unqualified approval. Sir RICHARD LUCE, who introduced the new policy to the meeting, ran over the changes involved in it. Among the special services there had been no alteration beyond the addition of an appendix on the provision of pathological services. The future relations of the voluntary hospitals and the new council hospitals under the control of the local authorities must be considered closely. The profession could not stand aside from council hospitals, but the terms on which the work should be undertaken were still to be decided. In the past the profession had always expressed a preference for the voluntary system, but there appeared to be some weakening from this view; some doctors held that the time for the voluntary hospitals was past and that their efficiency was declining, but there could be no doubt that a large number were still in favour of the system and held to it as an article of faith.

The provision of hospital beds where general practitioners could treat their own patients had been the subject of a resolution by the Panel Conference in 1928. To ascertain the practicability of such a scheme a questionaire had been sent out to 830 hospitals, of which 648 had replied. An analysis of the answers showed that none of the London or provincial general teaching hospitals had a local medical staff; that only two out of 109 of the larger general non-teaching hospitals had such a staff, and less than half of the general hospitals with under 100 beds. Opportunities for treatment of private patients in special wards were almost entirely confined to hospitals with less than 100 beds, so that there was little scope for the admission of general practitioners at present. There was no reason why they should not be given more opportunities in those hospitals which provided special wards and annexes, and it was believed that still more scope could be offered in the smaller hospitals—those with less than 100 beds. The new council hospitals would provide a fresh opening; it might be possible to obtain special accommodation for private patients and to treat others in the wards. If this were to be done the principle must be formulated now and admitted by the local authorities, or the opportunity would be passed over without forming any basis for future action.

Remuneration for members of the profession on hospital staffs was still in abeyance. Medical men were diffident about demanding payment where a hospital was in financial difficulties. Obviously, it would be much more satisfactory if the pressure came from some external body; the establishment of a precedent was the first step, and in two centres in the north this had been recognised. Speaking of the new policy as a whole, Sir RICHARD said it was simple, and lent itself to adaptation. It contained, he believed, no change of principle which would be unpleasing to the profession.

THE "COUNCIL" STIGMA.

A lively debate was introduced by Dr. M. W. RENTON (Dartford) over the hypothetical effect on the lay public of the term "council" as applied to hospitals. The ghost of Mother Poor-law, it seemed, had still power to cast her shadow over the future, and minds made sensitive by life in council houses and education at council schools might rebel against the ægis of the council in sickness at least, if not in health. But hardier opinions prevailed, and it was felt that the Briton would not be deterred by a mere generic term from attending a hospital which would doubtless boast a local name as well.

PLACE OF PRACTITIONER IN COUNCIL.

Dr. E. R. FOTHERGILL (Brighton) introduced an amendment suggesting an alternative scheme to be added to that proposed in the policy for the staffing of council hospitals. The policy provided for a full-time medical superintendent, a senior resident staff, a junior resident staff, a consultant visiting staff, and clinical assistants appointed from amongst practitioners of the area. Dr. Fothergill's alternative scheme differed from this only by proposing a whole or part-time medical superintendent, the omission of the senior resident staff, and the addition of a part-time general practitioner visiting staff to have responsible charge of beds and clinics. In small hospitals, Dr. Fothergill pointed out, a full-time medical superintendent might have so little work to do that he would be wasting a large part of his time, and a senior staff of men with the M.D. and M.S. degrees would develop a limited outlook if appointed permanently. A visiting staff of general practitioners would mean the admission of the family doctor to the hospital scheme, from which he had been excluded far too long.

In the discussion which followed the desirability for a senior resident staff, especially in areas where the accident incidence was high, was emphasised by Dr. J. T. D'EWART, and supported by Mr. N. BISHOP HARMAN. The view that the practitioner should be in a position to attend his patient in hospital met with considerable support from Dr. C. E. S. FLEMMING, who spoke of the disheartening and demoralising effects of losing touch with a patient at the most interesting stage of his illness. In many cases the practitioner was perfectly qualified to carry on the treatment if he had facilities at his disposal. By undertaking the post of clinical assistant a practitioner who wished to specialise would have opportunities to follow up the type of case in which he was interested. Mr. E. W. G. MASTERMAN saw an objection, however, to Dr. Fothergill's scheme in that it failed to state who was ultimately responsible for the patient: was it the general practitioner, the medical superintendent, or the consultant? The possibility that the practitioner might be engorging more than he could conveniently swallow was suggested by Mr. H. M. STRATFORD (Kensington). He pointed out that at a previous session the representatives had cheerfully accepted the dependents of the national insurance patients as their inevitable responsibility, and now they were clamouring for the onus of consultant's work at hospitals as well. He thought that Dr. Fothergill's amendment really embraced too much. Sir RICHARD LUCE said that he was quite prepared to accept Dr. Fothergill's amendment. The scheme of staffing proposed by the hospitals' committee would apply to the large municipal hospitals; that suggested by Dr. Fothergill was perfectly applicable to smaller hospitals. But he thought the "medical superintendent" should not be described as "whole or part-time," and that these words should be deleted. Dr. FOTHERGILL accepted this alteration, and his amendment was carried as an alternative scheme to that of the Council.

THE INCOME LIMIT.

Incorporated in a footnote of the hospital policy were the suggestions of the committee for an increase in the income limit in contributory schemes, the highest income not to exceed £350 or £7 a week. Dr. F. H. BODMAN (Bristol) proposed adherence to the old scale with £300 as the highest limit; an increase would result in loss of private practice to many practitioners. Other speakers considered that it would mean an encroachment on the junior consultant's fees as well. Sir ROBERT BOLAM explained that the raised limit was designed to include those foremen and higher workers in industrial areas who would really form the backbone of the scheme. A small difference in wages might be sufficient to put these workers outside the scheme and as they were few in number their inclusion would be no great loss. Mr. W. MCADAM ECCLES held that the effects of trade depression should be considered, those who were making a stout struggle against it should be encouraged by the opportunity to join such a scheme. Trade depression, however, falls alike on the unjust and the just, and Dr. R. M. MANWARING-WHITE was inclined to see its saddest effects on the junior consultant. Dr. N. E. WATERFIELD pointed out that to add to the numbers supporting contributory schemes would be to lessen the contributions to hospitals, since persons belonging to these schemes received special concessions in hospital.

The feeling of the meeting was opposed to an increase in the income limit. Dr. Bodman's views were endorsed by the meeting.

FREE CHOICE OF PRACTITIONER.

Dr. D. F. TODD proposed an amendment from Sunderland, suggesting that:

"Whether in the private rooms or wards of hospitals which have both public and private wards in the same building or in the special accommodation for private patients of a separate home or hospital provided exclusively for such patients, such home or hospital being an annexe of, or associated with a voluntary hospital having public wards, every private paying patient shall have 'free choice' of practitioner as his attendant, and of consultant and/or specialist, and that anything to the contrary in the proposed revised hospital policy shall be deleted."

Sir RICHARD LUCE said this amendment involved an alteration of the old hospital policy rather than the new. The feeling in most hospitals was against letting general practitioners into the general wards, and it had seemed advisable to limit their opportunities to patients treated in a separate annexe. Dr. H. B. BRACKENBURY opposed the motion on the ground of injustice to the consultant. The private wards contained the paying, and the general wards the non-paying patients; it was unfair that the general practitioner should retain control of all those that paid and hand over all those who must be treated for nothing. There was no reason why any hospital which desired to make the change suggested by Sunderland should not do so, and nothing to prevent the general practitioner from having such control of treatment as he and the consultant agreed between them. This part of the scheme, it should be remembered, applied only to those hospitals where private rooms or wards were found in the same building as public wards.

Dr. PETER MACDONALD supported the amendment; in the future it was hoped that members of hospital staffs would receive payment, so that the consultant would no longer be treating patients in the general wards for nothing. His view was shared by Dr. A. B. MURRAY, who felt any other attitude to be contrary to the policy of the Association. Opposition to the amendment was offered by Sir ROBERT BOLAM and Mr. BISHOP HARMAN, both of whom felt there was every necessary safeguard to the general practitioner in the policy as laid down. The paragraph in the policy which provoked discussion ran as follows:—

"When special accommodation for private patients takes the form of private rooms or wards in a hospital which has both public and private wards in the same building then: (*a*) if the hospital has a resident medical officer or officers and also a visiting staff which is ordinarily responsible for the care of all patients in the public wards—the patient should be under the responsible care of a member of the visiting staff, in association with the private practitioner of the patient who should have free access to the patient and should have such share of the responsibility and treatment of the patient as may be agreed upon between the member of the visiting staff and the private practitioner. . . ."

Dr. E. R. FOTHERGILL said that all the arguments used embodied two extremes. In a hospital with a visiting staff it was supposed that the staff assumed the view that all private wards were theirs and the general practitioner should not come into them, while the general practitioner was said to regard the private wards as his, and to demand the choice of consultant. The compromise was for the practitioner to go into the wards, and for the consultant to decide with him the responsibility that each should have in the case.

In replying to objections to the amendment Dr. TODD said that he was thinking chiefly of provincial hospitals where the staffs were often composed of general practitioners, who might even be in panel practice. It was most undesirable that a doctor should have to hand over his patient in hospital to a rival practitioner. Dr. BRACKENBURY asked whether Dr. Todd would be willing for his amendment to apply only to those hospitals where the staffs were composed of general practitioners. Dr. TODD agreed to the suggestion, but Dr. HAWTHORNE from the chair pointed out the pitfalls which awaited those who would draw a dividing line between general practitioner and consultant; on his proposal the amendment and the debated paragraph of the policy were referred back to the Council for further deliberation.

HOSPITAL RECORDS.

Another amendment moved by Dr. TODD, for Sunderland, referred to a short paragraph on the confidential nature of hospital records, and demanded the deletion of a phrase at the end reading "and access to them allowed solely to members of the visiting staff of the hospital." It was clear from the outset that what Dr. Todd, and indeed the meeting as a whole, wished to establish was that the general practitioner should also have free access to the records, while unauthorised persons should not. An interlude followed in which the meeting struggled for words to express this simple thought. After a complicated and painful labour the amendment was reborn and accepted in the following form: "These are confidential documents and access to them should only be allowed by the medical practitioner or practitioners responsible for the care of the patient."

OTHER AMENDMENTS.

Dr. F. RADCLIFFE, for Oldham, objected to certain paragraphs in the policy which estimated the number of panel patients treated at hospitals at 80–85 per cent., of indigent poor at 15 per cent., and of private patients or persons above the income limit at 5 per cent. He moved the deletion of these figures as being inaccurate in parts of the country other than that for which they were calculated. He deprecated

the inclusion in the scheme of figures which could be challenged and overset. Sir ROBERT BOLAM explained that the figures were carefully qualified by the context and were designed to give persons outside the profession some idea of the magnitude of the question. For the country as a whole the figures were not inaccurate, though they doubtless failed to cover the facts in certain industrial areas. The meeting decided that the paragraphs should be retained unaltered.

Dr. H. MACWILLIAM introduced an amendment not on the agenda referring to a paragraph in the Council's policy for hospitals with 100 or more beds. This read: "The visiting staff should be of a recognised competency, and should be proportionate to the number of beds in the hospital; a suitable ratio is about 1 to every 25 beds, or where out-patient departments exist the ratio of the staff should be greater." Dr. MACWILLIAM said that in a hospital of 1500 beds such a small number as 25 would be unreasonable, while if there were many chronic cases the consultant would have very little work. Dr. R. K. FORD (Preston) pointed out that the whole of this section, dealing with the standards for hospitals with 100 or more beds, was not applicable to the Council hospitals as drafted. The meeting therefore referred back this part of the policy to the Council for reconsideration.

Two amendments to postpone any decision on the policy until next year were defeated, and the hospital policy as amended was put to the meeting for approval and was accepted.

A General Medical Service.

Dr. J. W. BONE, who introduced this subject, was careful to point out that no scheme had as yet been formulated for a general medical service. All the Council wished to submit was a series of proposals which might form the basis of such a scheme. There had been a constant demand from the country of late years for health services supplied by the State and each of the political parties had had plans for adding to these services. It was necessary for the Association to be ready with proposals which voiced the opinion of the medical profession if coöperation became desirable. The proposals had their origin in a request from the Representative Body two years' previously that the Council should inquire into the increasing encroachments of one sort or another on medical practice. After hearing the report the Representative Body advised the Council to produce constructive proposals, and these were now set forth. The Ministry of Health had had no hand in their production, which was the work of seven consultants, five medical officers of health, and twelve general practitioners.

The persons included in such a scheme must be all the members of the community for certain services not obtainable otherwise, but a proportion of them would, of course, pay for such services. A second group, comprising the dependents of insured persons, would cover their service, either domiciliary or institutional, on some insurance plan. Finally, there were the indigent for whom the cost must be borne by the community. Both the family doctor and the consultant services would be provided on a contributory basis; institutional treatment would at present depend on the voluntary and council hospitals—the old poor-law institutions—since no other services were available. The financial aspect of the scheme had not yet been considered, because if the proposals were accepted that would require the attention of a different body. These proposals were merely a contribution to any national discussion on the subject in the future, and it was for the meeting to decide on the cardinal principles and help to set them out.

Dr. J. W. E. CORY (West Suffolk) suggested that the scheme would never have been formulated except under the threat of a whole-time medical service by the State, and that therefore the assertion in the Council's proposals "that it is in accordance with the beliefs and traditions of the medical profession" should be replaced by a declaration that the scheme was advanced only as a preferable alternative to a State medical service.

This frank proposal provoked much opposition; Dr. H. M. STRATFORD pointed out that the idea of a State medical service was at present only a bogy, and Dr. BRACKENBURY reminded the meeting that this was not the submission of a scheme requiring acceptance but an opportunity for discussion of principles which might ultimately have administrative effects. It was unwise to adopt an unconciliatory attitude at the outset. Dr. H. W. POOLER hoped that no statement would be allowed to go forward which implied that the medical profession was afraid of anything; least of all of a State medical service. In face of this opposition Dr. CORY's amendment perished.

Dr. A. B. MURRAY (Banff, Moray, and Nairn) proposed the alteration of the principle given in the proposals: "That the interposition of any third party between the doctor and the patient, so far as actual medical attendance is concerned, shall be as limited as possible," to: "That there shall be no interposition of any third party between the doctor and the patient so far as actual medical attendance is concerned." Dr. BONE spoke of several uncomfortable situations in which such interference was inevitable—for example, excessive prescribing or in malpraxis. The meeting rejected the amendment, and was addressed again by Dr. MURRAY on a different plea. He proposed that in any arrangements made for a communal or subsidised or insurance medical service the medical profession should be represented on the bodies responsible for the administrative and financial control of that service. The Council's proposals had required only free consultation with the medical profession by these bodies, but Dr. MURRAY suggested that this was inadequate. Dr. BRACKENBURY remarked that the two bodies in question appeared to be the Treasury and the Ministry of Health, on neither of which the profession could claim representation. The county councils or county borough councils were scarcely bodies on which a medical representative need sit. This amendment was also lost.

CARE OF THE INDIGENT.

An ingenious plan for the inclusion of indigent persons in the scheme had been provided by Dr. Brackenbury in the proposals, and was as follows:—

> "The cost of the domiciliary medical attendance of what has been known as the pauper class is known, or could easily be ascertained in every area, for, say, the last five years. This divided by the number of persons attended would give an average cost per person for domiciliary attendance. This amount per head could be paid by the Public Assistance Committee into the local national health insurance pool for each person referred by that committee for domiciliary attendance."

Dr. H. C. JONAS (Barnstaple) moved the deletion of this method from the proposals on the grounds that it had been decided not to consider financial questions as yet. The records kept by poor-law officers were not such as to make the method

practicable in any case, and at this stage it was impossible to arrive at any accurate figure.

Dr. BRACKENBURY said that it was difficult to find a method whereby these persons could be included in any scheme, and this had been formulated in reply to the question put by the Royal Commission: "Can you give us an illustration?" At the time no illustration had been forthcoming, but he believed this suggestion to be practicable. The pool, of course, would belong equally to paupers and non-paupers, and capitation fees would be redistributed from it irrespective of the class from which the patient came. Dr. JONAS said in reply that he was entirely in favour of the inclusion of the pauper class, but it was a difficult problem and should not be touched on in a document of this sort. It was decided to delete the passage.

A PROPHECY.

Among the proposals the following statement finds a place: "When all the work done in hospital is paid for, the scale of fees for outside work (which may be expected to diminish under this scheme) will naturally tend to adjust itself to the new circumstances." Dr. L. A. PARRY objected to this as misleading; if the hospital service were extended he said, outside work would be less than ever, and it would be impossible to charge lower fees. Dr. BONE replied that it was the only example of prophecy among the proposals. It was a case of the law of supply and demand; if members of the profession were properly paid for the work they did in hospital they would be in a position to charge less outside. This was one of the paragraphs in the proposals which would appeal to the general public, especially the middle classes. The statement was allowed to stand.

ADMINISTRATIVE DIFFICULTIES AND FINANCE.

Dr. E. R. FOTHERGILL, for Brighton, objected to the proposal that access to the local authorities should be through the medical officer of health, who, he thought, was not necessarily in sympathy with the practitioners of his area. The point introduced an interesting discussion on the relations usually existing between these parties, but the feeling of the meeting was that the local practitioners should have direct access to the county council or other administrative body when they so desired.

Dr. MILBANK-SMITH supported Dr. FOTHERGILL. The Insurance Act, he said, could never have been administered without statutory local medical committees; the scheme under discussion would be even more universal in its action. Under the proposals as they stood the medical officer of health would have to accept great responsibility. The county council would probably meet about four times in the year, and in the intervals he would often have to make decisions without consultation with that body. There should be a statutory medical committee with which he could confer on these points. Such a plan would be much simpler than one by which all small differences of opinion between the medical officer of health and the local practitioners were referred to the Council of the Association.

Dr. MIDDLETON MARTIN agreed that there was much to be said for the point of view adopted by Brighton, but he, as a medical officer of health, had discussed this question with his colleagues and they foresaw many difficulties in administration should Dr. Fothergill's amendment be carried. He thought that too many cooks might spoil the broth if the medical officers of health were forced to refer to a medical committee. The interests of the profession were the concern of the M.O.H., and he looked forward to the amicable coöperation of general practitioners with this officer. A division of opinions placed before the local authorities would complicate administration.

That the proposals of Brighton did not go far enough was the plaint of Dr. D. O. TWINING. Medical officers of health varied in their behaviour to other members of the profession in their area; some were Mussolinis and some were mice. Either variety was capable of reversing his opinions in a disconcerting manner, and one had been known to expect a revised decision to act in retrospect. If administration depended on one man in an area, efficiency depended solely on the character of that man; responsibility of such a kind was too great—it should depend on a local committee.

Dr. CHRISTINE MURRELL epitomised the arguments used in favour of the amendment when she said that though such direct access would probably be seldom needed, it was a useful power. The paragraph in the proposals was altered as suggested.

An estimate of the cost of the scheme had been introduced into a separate section of the proposals, calculated on a basis of figures obtained from the report of the Royal Commission on National Health Insurance in 1926. These figures, which had been included only for the sake of completeness, and to convey some idea of the financial aspect to the general public, were challenged by Dr. J. W. E. CORY on the grounds that they were not only out of date, but sketchy and misleading. A subsequent suggestion that the section might be left in if all the figures were deleted, though it gained the support of Dr. BRACKENBURY, was earnestly opposed by Mr. H. S. SOUTTAR, who protested against the emasculation of the scheme by the removal of a relevant part. The first question of any reasonable man, he said, when faced with these proposals would be: "How much will it cost?" and to put forward the scheme without giving some idea of its expense would be ridiculous. Dr. BONE agreed with him; no one would be satisfied by the mere statement that estimates had been made; he would want to know what they were. The section under discussion was retained unaltered.

Dr. A. S. WILSON proposed for Holland, Lincs., that the head of the local medical arrangements under these proposals should be a practitioner who had had a considerable number of years' experience of private medical practice. His argument was based on the ignorance, in some cases, of general practice by the medical officer of health, who might otherwise become the head of these local arrangements. The meeting, however, was not prepared to proceed to these lengths, and the amendment was lost.

Dr. BONE introduced an amendment to add to one of the principles laid down in the proposals—namely, "that medical benefits of the present National Health Insurance Acts should be extended so as to include the dependents of all persons insured thereunder." He suggested the insertion of the words "entitled to medical benefit" after "persons," since it was not intended to include "voluntary" subscribers who were not entitled to medical benefit. This alteration was approved.

An amendment to delay acceptance of the amended proposals, introduced by Dr. G. B. HILLMAN, was discussed very fully. It was stated that attendance at divisional meetings of the Association is often so poor that it is impossible to be sure that the

proposals have received the consideration of more than a fraction of the profession. For this, however, practitioners had no one but themselves to blame in the opinion of the meeting, since the proposals had been before them since April. The need for an early acceptance was urged by Dr. PETER MACDONALD, who said that the scheme should be available as propaganda as soon as possible, and by Dr. BONE, who thought that medical practitioners would not realise that the scheme had come into practical politics until these proposals were passed. The proposals, as amended, were eventually carried, whereupon Dr. BRACKENBURY introduced a statement to explain the absence of reference to insurance committees in the proposals, the motion being that the Council should be authorised to use the statement in any way which seemed likely to be useful.

The statement was as follows :—

Insurance committees, under that title or in their present form, are not mentioned in these proposals. The reason is that the ultimate aim of the Association is the unification—not merely the coördination—of the administration of all health services, nationally and locally. This, it seems, can only be accomplished by the establishment of a statutory committee (called in the present proposals the "Hospitals and Medical Services Committee") as an essential and integral part of the organisation of the work of county councils and county borough councils which in this way would exercise a general supervision, under regulations made by the Minister of Health, over the insurance medical services, and bring them into intimate relationship with hospital and institutional services provided or supported by the local authority. There is no reason, however, why the personnel of the new statutory committee should not, if after discussion this seems desirable, approximate still further to that of the existing insurance committees by including also appropriate representation of insured persons through approved societies. Meanwhile, in the not improbable event of some such proposals as those now put forward being adopted, not as a whole but piecemeal, it would be appropriate that extensions of the insurance service to the dependants of insured persons or the provision for such persons of a consultant and specialist service should, as an interim measure, be administered by insurance committees as now constituted. In that event the question of the relationship of the new provision for medical advice and treatment with other services provided by the local authority with a view to the promotion of economy and the prevention of reduplication would require careful consideration, and arrangements for the appointment of a chief medical officer in administrative charge of all the health services would be very desirable.

Dr. BRACKENBURY pointed out that this statement changed nothing in the scheme, and was merely designed to reply to the inquiries of insurance committees on their exclusion from the proposals. The committee suggested it would resemble an insurance committee, but the representation on it would be in other proportions.

Dr. H. C. BRISTOWE suggested that all of the statement following "institutional services provided by the local authority" should be deleted as irrelevant. Dr. H. G. DAIN and Dr. MACDONALD opposed this suggestion, and were able to put the advantages of the insurance committees before the meeting, as bodies usually powerfully influenced by the weight of medical opinion. Dr. BRISTOWE was induced to withdraw his amendment, and the original statement was referred back to the Council for consideration.

(To be concluded.)

ROYAL FREE HOSPITAL.—During the past year the total expenditure was £80,545, and the income £73,006; patients and their societies paid £19,346. The bank overdraft exceeded £30,000. Charges in the out-patients' department have been increased (average per attendance, 1*s.* 11½*d.*); in-patients (average daily number, 233) cost £4 8*s.* per week. It was expected that this year bank interest would approximate to £2000. X ray films are now being stored for safety's sake in an external building.

MEDICINE AND THE LAW.

The Coroners Amendment Act: an Interesting Point.

His Honour Judge Hill-Kelly, sitting at Redhill County Court on July 16th, gave judgment in the case (heard last month) in which Dr. David Low Greig, of Caterham, claimed £22 1*s.* for attending a post-mortem examination and giving evidence at an inquest in respect of the deaths of seven persons at Caterham, on Nov. 8th last, from Mr. F. J. Nightingale, of Reigate, the Coroner for East Surrey. When the action was heard, Mr. H. C. Dickens (for Dr. Greig and the Medical Defence Union) explained that the dispute was a friendly one, as a result of which it was hoped to get His Honour's interpretation of Section 23 of the Coroners Amendment Act, 1926. Mr. Milner Holland appeared for Mr. Nightingale and the Surrey County Council.

His Honour recalled that last November a number of persons were killed at Caterham as the result of an accident to an aeroplane. One of those persons was taken to the house of the plaintiff, there dying the same day. Later, defendant sent an officer to the plaintiff requesting him to go to a mortuary and view the bodies of the other six persons involved in the accident, to determine the cause of death in each case, and also to obtain details for purposes of identification. On Nov. 7th plaintiff attended the mortuary and examined the bodies. Defendant then instructed plaintiff to attend the inquest to be held by him on Nov. 8th. Plaintiff attended as instructed, and gave evidence as to the cause of death of each of the six persons whose bodies he had examined at the mortuary, and also as to the cause of death of the person who died at his house. Having done so, plaintiff was bound over to attend at an adjournment of the inquiry. He attended on that day. The inquiry was held by the defendant sitting as coroner, together with a jury. The course which was taken appeared to have been sanctioned by authority—namely, that where more than one person was killed at the same time, and apparently from the same cause, only one jury was sworn, and the inquiry into all the deaths was taken at one and the same time. Evidence had been given to the effect that the inquiry touching the deaths of the seven persons referred to was made at one and the same time. In those circumstances plaintiff claimed the sum of £22 1*s.*, contending that he was entitled to one and a half guineas in respect of each of the dead persons. Defendant contended that plaintiff attended to give evidence at only one inquest and was entitled to only one sum of one and a half guineas—that was to say, three guineas in all (in respect of the post-mortem and the inquest). The question thus raised depended on the proper construction of Section 23 of the Coroners Amendment Act of 1926, dealing with fees payable to a qualified medical practitioner. The section provided that a doctor should be remunerated in three different sets of circumstances—first, for his attendance at an inquiry without a post-mortem examination; secondly, for a post-mortem examination without afterwards attending an inquest; and thirdly, for making a post-mortem and giving evidence. In order to consider the section it was proper to have regard to the whole of it. It provided that a medical practitioner should be entitled to three guineas for making a post-mortem and attending the inquest to give evidence. Remarking that much depended on the reading of the Act on the interpretation of the word "inquest," His Honour

said it was a common practice for coroners to hold inquiries into the deaths of two or more persons at one and the same time, but in his interpretation of the law he thought there were as many inquests as there were dead bodies. The language of the Coroners Act of 1887 and the Amendment Act of 1926 seemed throughout, with one exception, to contemplate in the use of the word "inquest," one inquiry touching the death of one single person. The exception was in respect of two or more persons who die from the same accident and lay in different parishes or areas under different jurisdictions. In that case the Secretary of State might give an order for the removal of one of the bodies from one area to the other for the inquest. What was significant in that section was that the word used was "inquests"—in the plural. Having quoted a case in the King's Bench having a bearing on this interpretation, His Honour said that the result of that interpretation was that plaintiff was entitled to recover from the defendant the amount claimed—£22 1*s*. and he gave judgment for the plaintiff for that amount. It might appear a strange result of the case that a medical practitioner was entitled to so large a sum in respect of one inquiry, but the fact that the circumstances were unusual ought not to affect the interpretation of the Act of Parliament: no question could arise as to its reasonableness.

His Honour, in giving judgment, awarded costs on Scale C, and agreed to a stay of execution for 21 days, it having been intimated that the case may go to appeal.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

OVER 5000 delegates attended the annual meeting of the American Medical Association this year in Detroit. Of these nearly one-third came from the State of Michigan.

SOCIALISATION OF MEDICINE.

The retiring presidential address by Dr. M. L. Harris dealt with problems of medical economics. The organisation of the Public Medical Service Association in England was held up to delegates as a horrible example of "what may be expected to happen to the medical profession when it loses control of its own business." Similar interference is found in Belgium and in Prussia. "Medicine is being besieged on every hand by forces that are constantly growing stronger and stronger." As a remedy for this trend towards "socialisation," Dr. Harris proposes that county medical societies incorporate and organise for business purposes, and then establish medical centres owned, controlled, and managed by the profession, where all who cannot pay regular fees may receive adequate treatment at charges which are within their means.

The report of the secretary, Dr. Olin West, also called for aggressive organisation by professional groups, and urged the importance of these groups becoming leaders in the communities in matters of health, and in particular in popular health education. The central organisation in Chicago is already engaged through its Bureau of Health and Public Instruction in these activities. The work of this bureau was warmly approved.

ABUSE OF MEDICAL SERVICE TO HOSPITALS.

The new president of the association, Dr. William Gerry Morgan, dealt in his address with the history and evolution of charitable hospitals and dispensaries. He showed how in their origin they represented a coöperative enterprise, the charitable public providing the physical needs and the profession giving free of charge their professional skill. Now the simple asylum for the indigent sick has become in part the elaborate nursing hotel of the well-to-do, in part the costly laboratory of the surgeon, and in part a necessary instrument of medical education. The fact has been lost sight of that the physician's contribution is still the gift of his skill to the sick person, and that this contribution is not a part of hospital property to be donated or bartered according to the corporate judgment of its trustees. There are, of course, exceptions, such as private hospitals and hospitals constructed and operated entirely by public funds.

Dr. Morgan's conclusions, which are to be considered as a basis for a campaign of re-education of both the lāity and the profession, include the following:—

(*a*) The physician is no more obligated to provide for the care of the indigent sick than his fellow citizen.

(*b*) In mutual charitable undertakings for the care of the sick, each citizen contributes what he has: the laymen, physical necessities; the physician, professional skill. But each has a right to protect himself from exploitation, and to judge of the merit of the recipients of his bounty.

(*c*) When a hospital offers its facilities to a mixed clientele, pay, part pay, and pauper, the distinction between the sources of those facilities should be clearly recognised. The physical equipment and service is of general public origin, and their uses may be sold or given away in the discretion of lay boards; but the professional facilities are, and always must be, the contribution of the medical staff as individuals and cannot become in any sense the property of the institution.

(*d*) When a hospital is owned and operated by government, and supported by taxation, to which the medical profession contributes its due proportion, medical attendance should be paid for by taxation, along with all the other facilities supplied by the institution.

(*e*) No hospital instituted and supported by public philanthropy or community coöperation of any kind should be premitted to increase its revenues, and so reduce its financial burden on the public, by any system of collecting fees for medical attendance, and thus engaging in the corporate practice of medicine.

TARIFFS AND MEDICAL APPLIANCES.

The Board of Trustees of the Association reported on the increased tariff which despite their efforts now falls upon a large number of articles "necessary for the diagnosis and treatment of disease." The duty on surgical instruments is increased from 45 per cent. to 55 per cent. (but not to 75 per cent. as urged by American manufacturers). The tariff on pharmaceutical or surgical instruments wholly or chiefly of glass is increased from 65 per cent. to 85 per cent., and so on. They add that it will be a matter of regret if the increased duty is made an excuse for excessive increases in retail prices.

MOTORING FATALITIES.

The House of Delegates took notice of the "steadily mounting death-rate from motor vehicle accidents, and of the fact that only ten States and the District of Columbia have mandatory examinations of drivers before granting licences. "They resolved that the association should use its influence to secure legislation in all States for physical examination, and that a committee study the subject further and formulate a model standard of physical fitness for drivers that can be recommended to State legislatures.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

IRISH MEDICAL COMMITTEES.

A MEETING of the Irish Medical Committee was held in Dublin on July 16th, Dr. J. M. Day presiding. It was reported that the National Health Insurance Commission had recently made certain deductions from the payments made to medical certifiers for furnishing certificates of medical incapacity. The rates of remuneration had originally been fixed by agreement between the National Health Insurance Commission and the Irish Medical Committee, and the Committee expressed the opinion that no change should have been made without consultation with it. A member reported that in his district a post of medical attendant to a station of the Civic Guard had recently been filled by inviting medical men in the neighbourhood to state the terms on which they would be prepared to give attendance, the post being given to the candidate who offered the lowest terms. The Committee strongly disapproved of such a method of appointment, as likely to lower the standard of medical attendance and as contrary to the principles of the profession. It directed a protest to be sent to the Minister for Justice.

A CONFERENCE ON PUBLIC HEALTH.

Mr. R. Mulcahy, Minister for Local Government and Public Health in the Irish Free State, recently summoned a conference to discuss questions concerning his department. The conference was held early this month in the Mansion House, Dublin, and was attended by representatives, including many medical officers of health, of all the local authorities dealing with health administration. The Minister delivered a stimulating opening address pointing out that the growth of public health work depended primarily on an educated public opinion on sanitary and health matters. Only public opinion could provide the driving force and clear the way for improvement. Dr. J. C. Saunders, medical officer of health for the City of Cork, read a paper on the methods by which health education could be promoted. Communal hygiene, he contended, should be national rather than local, and should be put into effect by a central organisation. The insanitary condition of the schools, especially in rural areas, was a great blot on the social system. The teaching of preventive medicine called for a more important place in the curriculum at medical schools. Dr. O'Higgins, county medical officer of health, Meath, and Dr. McDonnell, medical inspector, Local Government Department, spoke of the need of educating the public and the methods by which this could be done.

Dr. R. Conelly, medical officer of health for the county of Cork, opened a discussion on county health administration with particular reference to the functions of the county medical officer of health. He regarded the supervision of the production and handling of food, especially meat and milk, as of great importance. Where the circumstances of the area made it feasible, by-laws providing for a system of inspection and stamping of all meat before sale should be introduced. The annual report of the county medical officer of health should show the character and extent of the health work done over a given period.

Dr. Mary O'Leary, school medical officer for the county borough of Dublin, read a paper on the Health of the School Child. She urged the need of open-air schools and nursery schools, and in the meantime the establishment of summer convalescent homes or camps. The discussions aroused lively interest, both among the medical officers and the lay members of the local authorities, and the Minister has cause to congratulate himself on the success of the conference.

QUEEN'S UNIVERSITY OF BELFAST.

Presiding at the summer graduation ceremony of Queen's University on July 10th, the Chancellor, Lord Londonderry, said that this was a suitable occasion to "take stock," for the University came of age this year. Twenty-one years have elapsed since the Queen's College attained university rank, and the number of students has increased from 600 to almost 1400. The revenue of the University has not, however, grown at the same rate. The report of the University Grants Committee last year pointed out that Queen's was doing more work on less money than any university in Britain, and it also laid stress on the fact that Queen's was receiving less help from the Government, local authorities, and private benefactors. The six British universities with which it was compared received in gifts from private persons during the past five years sums varying from £479,000, the largest figure, to £66,000, the lowest. Queen's, during the same period, received in private gifts £2435. Lord Londonderry said that a student in any university only paid a third of what his education cost; he appealed to his hearers not to forget this when they left. He hoped that all would join the recently formed Queen's Association.

Before conferring the degrees the Chancellor referred with regret to the death of Dr. T. I. Candy, which had taken place between the reception and acceptance of his thesis for the M.D. degree of the University.

In addition to the names published in THE LANCET of June 28th Samuel Nevin received the degree of M.D., with gold medal. The Adami Medal in Pathology was awarded to William S. Campbell; the Symington Medal in anatomy to David C. Porter, and the Sinclair Medal in Surgery to Arthur G. Ross.

The headmasters of the secondary schools in Northern Ireland consider that the standard of Latin set in the Matriculation for the Faculty of Medicine and in the Senior Certificate examination of the Ministry of Education too difficult for the average schoolboy. The Medical Faculty, unwilling to admit students without some knowledge of Latin, have met the difficulty by new regulations, passed by the Senate, whereby after the session 1931–32 candidates are required to have studied Latin and to have obtained therein 40 per cent. at the Junior Certificate examination or at an equivalent examination. The Senate also adopted regulations for the recently instituted Diploma in Psychological Medicine.

The examinations for medical degrees will henceforth be held in June and December and not in March and June, and the session in the Medical Faculty will commence in the beginning of October and not in the middle of the month.

ROYAL SOUTHERN HOSPITAL, LIVERPOOL.—The number of out-patient attendances last year increased by nearly 10,000 notwithstanding efforts to use the department as a consultative centre for the treatment only of the more serious cases referred by doctors. The principal increases were in the electrotherapeutic and massage and actinotherapy departments. The surgical work is increasing so rapidly that plans have been prepared for the extension at a cost of £25,000 of the operating theatre and X ray unit. In the last five years the number of radiograms taken (13,246) has nearly doubled. There were close upon 17,000 attendances for massage.

THE BEIT MEMORIAL FELLOWSHIPS.

NEW ELECTIONS.

IN 1909 Sir Otto Beit made a gift of £230,000 for the endowment, not of buildings, but of men and women who were equipped and anxious to devote a few years of their lives to research in medicine and the allied sciences, but lacked the means to do so. At first the values of the Fellowships were £350 per annum for three years for Junior Fellows; £400 for fourth year Fellows; and £500 for three years for Senior Fellows. These stipends were increased in 1927 respectively to £400, £500 and £700.

The trustees of the fund are assisted in the selection of candidates by a scientific advisory board, and in the annual report for 1929 this board expresses the opinion, in which all will concur, that the founder has every reason to be satisfied with the results obtained during the first 20 years of the life of the trust. The total number of Fellows elected up to and including 1930 is 138.

Ignoring the more recent appointments, the report analyses the subsequent career of the 101 Fellows appointed up to 1925. We made a similar analysis in THE LANCET (1926, ii., 1019) of the first 70 Fellows, and it is interesting to see that the more recently appointed Fellows follow much the same paths as their distinguished predecessors.

Of the 79 men elected to Fellowships up to 1925, seven died at a relatively early age. Four have received the F.R.S., and 16 have been appointed to University Professorships. Most of the remainder occupy whole-time posts for teaching, research, or scientific work. Of the total of 52 who held medical qualifications when appointed, 13 have passed into medical practice, consulting or otherwise, but the majority of these are continuing scientific work.

Of the 22 women elected during the same period, a few have married, but all continued for many years the work of research and many are still thus engaged. That they hold, or have held, such positions as members of the scientific staff of the Lister Institute; university lectureships in biochemistry; pathologist and bacteriologist to general hospitals and boards of health; head of a department in an institute for medical research; principal of a horticultural college; physicians to children's hospitals, and holders of Rockefeller Medical Fellowships, is sufficient proof of the value to them and to the community of their training.

This year a Senior Fellowship has been given to Dr. R. J. Lythgoe, who is working on the special senses, and fourth year Fellowships respectively to Mr. Philip Eggleton, M.Sc., for work on the different types of contractile tissues and their metabolism, and to Dr. F. R. Winton, who is investigating the physiology and pharmacology of urinary secretion at Cambridge.

The Junior Fellowships for 1930 are allocated as follows:—

Frederick Horace Smirk, M.D. Manch., M.R.C.P. Lond. (1) To study the functional pathology and physiology of diuresis from a biochemical standpoint; (2) to study the functional pathology of plethoras, anæmias, and œdemas.

Gordon Roy Cameron, M.B., D.Sc. Melbourne. To complete work on the histological identification of calcium salts in pathological deposits and to commence study of inflammation in invertebrates. Proposes to investigate reaction of tissues of earthworm to foreign bodies, parasites and bacteria.

John McMichael, M.B., M.R.C.P. Edin. For a continuation of present studies on the inter-relationships of liver and splenic disease and on diseases of portal vessels and other vessel changes in liver disease.

Robert Percival Cook, B.Sc. Melbourne, Ph.D. Camb. For a study of bacterial metabolism and its relation to the specific action between host and bacterial parasite. Proposes to study metabolism of various types of bacteria by (1) chemical changes produced during actual growth in chemically defined media; (2) to study the individual enzyme systems of the bacterial cell.

Norman Urquhart Meldrum, B.Sc. Edin. For (1) a study of the so-called reversible denaturation of hæmaglobin. Intends to determine the influence of factors such as dilution, addition of foreign proteins and influence of acidity on the equilibrium between methæmoglobin, globin, and hæmatin (2) to measure formation of sulphydryl groups in various types of protein denaturation.

David Reginald Piper Murray, B.A.Camb. For comparison of the two types of proteolytic enzyme characteristic of the tissues and organs and of the digestive tract. Investigation to be based on studies of kinetics.

George Norman Myers, M.Sc., M.B. Durh. The curative action of digitalis, its glucosides and allies, in genera toxæmia, and in conditions of shock.

Charles Amos Ashford, B.A. Camb. For studies in (*a*) the metabolism of nervous tissue; and (*b*) mode of action of vitamin D, with special reference to hypervitaminosis D.

Dr. Smirk will work in London at the medical unit of University College Hospital, Dr. Cameron at the Graham Laboratory of University College Medical School. Dr. John McMichael is to work at Aberdeen in the department of medicine of the University and Dr. Myers in the Pharmacological Laboratories at Cambridge. The other four new Junior Fellows propose to carry on their research at the Sir William Dunn Institute at Cambridge.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. E. B. Kenny is placed on the retd. list.

The following appointments are notified: Surg. Comdrs. E. St. G. S. Goodwin to *Suffolk*, and P. L. Gibson to *Malabar*, for R.N. Hospital, Bermuda; A. H. Joy to *Pembroke*, for R.M. Infirmary, Chatham; C. H. M. Gimlett to *Dolphin*; and R. A. W. Ford to *Coventry*.

Surg. Lts. T. B. Lynach to *Nelson*; W. D. M. Sim to *Cambrian*; W. V. Beach to *Adamant*; R. L. G. Proctor to *Vivid*, for R.N. Hospital, Plymouth; and T. A. Cochran to *Greenwich*.

ROYAL NAVAL VOLUNTEER RESERVE.

Prob. Surg. Sub.-Lt. J. D. Lendrum to be Surg. Sub.-Lt.

Surg. Lt. H. M. Willoughby to *Albury*.

ROYAL ARMY MEDICAL CORPS.

Maj. and Bt. Lt.-Col. H. M. J. Perry, R.A.M.C., to be Professor at the Royal Army Medical College.

Col. M. H. Babington, late R.A.M.C., retires on retd. pay.

Col. G. T. Brierley, on attaining the age for compulsory retirement, retires on retd. pay.

Maj. and Bt. Lt.-Col. H. M. J. Perry, from the secd. list, is restd. to the estabt.

Capt. J. C. Coutts to be Maj. (prov.).

Lt. (on prob.) W. A. Y. Knight, from the secd. list, is restd. to the estabt.

ARMY DENTAL CORPS.

Capt. P. E. Brown to be Maj.

Capt. J. L. Garrard to be Maj. (prov.).

Capt. G. A. Ballantyne, relinquishes his comm. on appt. to the R.A.F.

ARMY RESERVE OF OFFICERS.

Capt. W. W. Phillips from Supp. Res. of Offs., to be Capt.

TERRITORIAL ARMY.

Capt. W. A. Jackman to be Maj.

Lt. E. A. L. Murphy to be Capt.

C. N. Suter (late Cadet, Edin. Academy Contgt., Jun. Div. O.T.C.) to be Lt.

Capt. G. Williams resigns his commn.

Lt. J. B. Dedman resigns his commn.

ROYAL AIR FORCE.

Squadron-Leader H. J. Proctor (Major, Army Dental Corps) relinquishes his temporary comm. on return to Army duty.

DEATHS IN THE SERVICES.

Lt.-Col. Sidney Browning Smith, C.M.G., late I.M.S., who, as we announced last week, died on July 13th, after a long illness, at Lyncroft, Otford, Kent, at the age of 6[illegible] was the son of Dr. Thomas Browning Smith of Sittingbourne and was educated at Epsom College and St. Bartholomew's Hospital. After qualifying with the Conjoint diploma he joined the Indian Medical Service and took part in the Chitral operations with Sir Francis Younghusband (mentioned in despatches and medal with clasp). After the Waziristan operations of 1901–02 he was appointed district plague officer at Amritsar and later chief plague officer in the Punjab. He embodied his experiences in this connexion in "Plague in India," which he published in 1904. In the late war he served on the western front and in Egypt (mentioned in despatches and made C.M.G.) and he was the organiser of the Mount Dore Hospital for Indian troops at Bournemouth and the clearing station at Karachi. He retired in 1921.

CORRESPONDENCE

THE INTERPRETATION OF DENTAL RADIOGRAMS.

To the Editor of THE LANCET.

SIR,—The letter by Dr. Brailsford in your last issue contains several remarkable statements. His suggestion that the conception of dental sepsis as a factor in the causation of general disease was forced on a reluctant and hostile dental profession by the medical profession is a ludicrous travesty of the facts. It is true that the credit for formulating this view was due to Dr. William Hunter. At first, no doubt, his views were received with incredulity by both doctors and dentists, but they very quickly became accepted by both, and it is much nearer the mark to say that Dr. Hunter's work has received the strong support of the dental profession as a whole almost from the first. Over 20 years ago, when I was a dental student, the doctrine of dental sepsis in relation to general disease was vigorously taught at the Royal Dental Hospital, and the cult of the clean mouth practised with equal vigour. Indeed, one may say fairly that for the last two decades in this country the dental profession has accepted Hunter's views as unquestioned in the same way as the doctor has accepted the principles of Listerism. It is true that some dentists have tried to infuse a note of caution because of the many cases they see in which the removal of undoubted dental sepsis has failed to relieve the patient who has thus had the burden of an edentulous mouth added to his other ailments. An uncritical acceptance of a theory is even worse than scepticism, and I would suggest that it is to our credit that we have tried to rationalise Hunter's work and to make the treatment of dental sepsis as a therapeutic measure an instrument of greater precision. The dental surgeons "of repute" (though I have yet to meet them) may be fairly balanced by those doctors who still ignore the significance of dental sepsis.

I fully appreciate the work of radiologists in demonstrating the existence of dental lesions otherwise not easily discoverable, but I would point out that radiology owes much to the pioneer work of dentists in this field, and that many of the advances in the assessment of the significance of dental radiograms has been made by dentists, whether practising radiology exclusively or not. In your editorial you say that dentists in general do not attach much importance to the reports on radiograms. It is truly a commonplace in conversation among dentists that the reports which usually accompany a set of radiograms, while useful no doubt to the medical practitioner, tell the dentist singularly little, and often require considerable correction when correlated with the clinical findings. How many radiologists ever ask the dentist in his turn to furnish a report showing the clinical or post-extraction findings so that he may know how far his interpretations are borne out? I have not heard of any who do this.

Those who study the actual conditions as revealed during the course of treatment know that there is by no means an exact correspondence between these and the appearances shown in the radiogram. If Dr. Brailsford would refer to Weston Price's book on dental infections he will find there an instructive chapter on the capabilities and limitations of X rays. In THE LANCET (1929, ii., 375) Dr. D. A. Imrie, who is a radiologist possessing a dental qualification, tried to correlate the X ray and pathological findings of some cases of dental infection, but such laudable efforts are unfortunately rare. The usual reports obtained from radiologists not possessing the familiarity with dental conditions which a dental training brings with it, follow a stereotyped line. They often contain inaccuracies and reveal clearly that the writers of them are ill-acquainted with the elements of the anatomy and pathology of the teeth and jaws. Dr. Brailsford implies that the dentist who does not limit himself to radiology is technically not equipped to take good radiograms. As a teacher of dentistry I see a large number of dental radiograms, and among them some bad ones. Radiologists, radiographers, and dentists have all contributed bad ones, but I should certainly not say that dentists sin in this respect more than others. On the contrary, dentists who take their own radiograms without specialising in this subject are usually quite competent to do so, and produce radiograms free from distortion, and with the light and shadow well contrasted. I know that dental students soon learn to recognise the essential points in a radiogram. Such an error as that described by Dr. Brailsford, of mistaking a large apical abscess for the antrum must surely be uncommon. I myself have seen the mental foramen solemnly described as an abscess in a report by a radiologist. I have seen a cyst involving an upper lateral incisor and showing as a large area of rarefaction in the film, overlooked in the radiologist's report, because it had evidently been mistaken for the antrum, though a very elementary knowledge of the anatomy of the jaws should have made it clear that the antrum does not extend to the incisor region. But recriminations of this sort are not very helpful. I look forward to a time when every dentist will possess his X ray apparatus just as he possesses a dental engine, for apart from the routine examination of the mouth for the investigation of dental sepsis, radiograms are very helpful in the everyday routine of dental practice, and the dentist who cannot take his own radiograms is undoubtedly handicapped. The radiologist who takes really fine radiograms and can accompany them with a report which is accurate and helpful will always find plenty of dental work referred to him both by doctors and dentists. I regard Mr. Henry's articles as conveying an extremely lucid exposition of a difficult subject, the more valuable because of his all-round knowledge of dental surgery and pathology.

I am, Sir, yours faithfully,

Brook-street, W., July 19th, 1930. A. T. PITTS.

MENINGO-ENCEPHALITIS AND HERPES ZOSTER.

To the Editor of THE LANCET.

SIR,—Apropos of the article in THE LANCET of July 12th by Drs. Schiff and Brain, entitled "Acute Meningo-encephalitis associated with Herpes Zoster," you may be interested in the following account of a case I saw for the first time a week ago.

A healthy looking married woman of 30 went to her doctor on June 18th complaining of weakness in the right arm and numbness and tingling in the fingers of the same side which had spread up the arm as far as the shoulder. On the 25th she was somewhat better; the abnormal sensations being confined to the thumb, index, and little fingers. On the 30th the whole forearm was involved, but

the greatest amount of paræsthesia was still in these fingers. In addition there was a patch of herpes over the seventh cervical vertebra. On July 6th pain developed in the right heel accompanied by numbness, still present on the 11th when she saw me.

I found herpes over the seventh cervical vertebra as stated and also in front over the right sterno-clavicular joint, with a few vesicles extending across the mid-line. The face was normal. There was marked weakness in the right grasp and in the triceps. There was anæsthesia to light touch, to vibration, to temperature, and to pinprick from the tips of the fingers to the upper arm at shoulder level. In addition there was definite wobbling in the finger-nose test on that side. The right leg showed similar sensory changes as high as the knee. I could detect no ataxia in the leg; the heel was painful to stand on. The reflexes were all normal; the abdominals could not be elicited. The left side was normal.

There had been a certain amount of headache since the illness began but not at all severe. There had been no eye trouble, and she was feeling much better than she had been.

I saw the patient again to-day, when I found that marked improvement had taken place. The anæsthesia was confined to the right thumb and index; the grasp was still weak but greatly better than a week ago. An examination of the C.S.F. was not done; it did not seem worth while in an illness already over three weeks old when I first saw the patient. I am, Sir, yours faithfully,

Coventry, July 18th, 1930. W. FRASER ANNAND.

EFFECT OF RADIUM ON CARCINOMA.

To the Editor of THE LANCET.

SIR,—The question whether it is possible to stimulate malignant cells by means of irradiation, and if so, whether that stimulation is direct or indirect, is still in dispute, but every surgeon, I think, will agree that if a malignant growth is cut into with a knife, needle, or any other instrument, cells may be disseminated, and, moreover, their actual growth may be stimulated by the tissue juices created as a result of the trauma.

Mr. Romanis, in his interesting note, has not excluded these possibilities, and I would suggest therefore that the only thing he can deduce is that the radium did not kill the cells that were in the track of the needle. If radium plaques had been used and the growth had been increased near those plaques, there would have been more justification for assuming that irradiation could in some cases stimulate malignant growth.

I am, Sir, yours faithfully,

Harley-street W., July 19th. MALCOLM DONALDSON.

CONGENITAL ATRESIA OF THE ŒSOPHAGUS.

To the Editor of THE LANCET.

SIR,—A few days before Dr. Polson's paper on atresia of the œsophagus was published in your last issue I attended at the delivery of a child that presented this as well as several other congenital abnormalities. He was born on July 12th, at full time after a pregnancy and labour that presented no abnormality of note. The mother was a primipara, aged 22. The baby appeared to be fairly healthy at birth and weighed 6½ lb. A few hours after birth it seemed to have considerable difficulty with respiration and quantities of rather viscid froth were brought up with difficulty. At intervals it became cyanosed. The quantity of froth prevented any attempt at feeding. On account of an imperforate anus the child was removed to Rochford Hospital, where Dr. Newey attempted to find the rectum by the perineal route but without success. The child died on July 15th. The following day I was present at an autopsy carried out by Dr. Newey. The condition of the œsophagus was almost exactly as shown in the illustration given by Dr. Polson. In my case there was not so much hypertrophy and dilatation of the upper portion as he shows, and the lower portion opened into the trachea at the level of the bifurcation. In addition the child presented the following congenital abnormalities: (1) imperforate anus with complete absence of the rectum, the pelvic colon ending blindly; (2) hydronephrosis of the right kidney with no connexion between pelvis and ureter; (3) patent foramen ovale; (4) absence of the right thumb; and (5) abduction of the right hand at the wrist. The lungs showed a marked degree of interstitial emphysema arising apparently from the difficulty with respiration.

I am, Sir, yours faithfully,

C. P. DONNISON, M.B., B.S. Lond.

South Benfleet, Essex, July 21st, 1930.

THE OUT-PATIENT QUEUE.

To the Editor of THE LANCET.

SIR,—The cure of the overcrowded out-patient department to which you referred last week is largely in the hands of the management of the hospital. It is the indiscriminate welcome accorded to all and sundry who apply for treatment that is at the root of the trouble. I would suggest that, except for emergencies, no patient be seen in an out-patient department unless he brings a letter from a doctor or proves that he is not insured under the National Health Insurance Act, and is too poor to afford even the most modest doctor's fee.

I am, Sir, yours faithfully,

Westbourne Park-road, W., July 19th. J. COHEN.

THE PROPER STRAPPING OF THE CHEST.

To the Editor of THE LANCET.

SIR,—Dr. C. W. Chapman, in his letter on Left Inframammary Pain which appears in your issue of June 28th (p. 1434), properly calls attention to the value of strapping of the chest in those cases where the pain is manifestly made worse by the movements of respiration. But in his description of how strapping should be done he leaves out the important point that the strips should be drawn tight and pressed firmly into position while the patient's chest is in the position of *full expiration*. Unless this detail is attended to, the movements of the side are little affected by the presence of strapping on the surface. Another point not mentioned, but no doubt assumed, is that the straps should run horizontally round the side of the chest, thus crossing the line of two or more ribs, and so increasing the fixation aimed at.

I feel like apologising, Sir, for thus mentioning such apparently small points, but it is the attention to details in many therapeutic measures that makes all the difference between success and failure.

I am, Sir, yours, faithfully,

Toronto, July 8th, 1930. R. D. RUDOLF.

OPENING OF BETHLEM ROYAL HOSPITAL.—The new hospital at Monk's Orchard, Beckenham, of which the foundation-stone was laid in July, 1928, by Prince Arthur of Connaught, was opened by the Queen recently. The hospital, which has cost £450,000, stands in its own park of 200 acres, a few minutes' walk from Eden Park station (S.R.) and on the ten mile circle drawn round Charing Cross. Patients will for the most part have separate bedrooms, with a few four- and five-bed wards for special purposes. The move from Lambeth will soon follow. The cost of laboratories for routine and research work has been met by a gift from Lord Wakefield.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

HEALTH ADMINISTRATION IN SCOTLAND.

THE House of Commons on July 14th considered in Committee of Supply a vote of £1,651,592 to complete the sum of £2,791,592 required for the salaries and expenses of the Department of Health for Scotland. Mr. HERBERT DUNNICO was in the chair.

Mr. ADAMSON (Secretary of State for Scotland), in moving the vote, referred to a few of the outstanding figures in the vital statistics for 1929. He said the birth-rate was 19·02, the lowest since compulsory registration was introduced in 1855. The death-rate was 14·5 per 1000, slightly higher than in the previous year, but this was influenced by an epidemic of influenza in the first quarter, during which respiratory diseases had an adverse effect on the infantile mortality —86·8 per 1000 births. The maternal mortality-rate for 1929 was 6·9 per 1000 births, as compared with 7·0 for the preceding year, the schemes of maternity and child welfare showing little result. Investigations were being made into all deaths of married women during pregnancy, or within four weeks of its termination. There was already a quite definite indication of the need for more complete medical supervision. An effort would be made to secure an adequate antenatal service under the Local Government (Scotland) Act, 1929. But the mothers themselves must coöperate by making a fuller use of the services provided, and this would have to be secured by stimulating their interest in these services through education.

DECLINE OF TUBERCULOSIS.

Here he was able to present a more encouraging picture. The death-rate from all forms of tuberculosis, 94 per 100,000 of the population, was the lowest yet recorded, being 3 per 100,000 less than the record figure for 1928. Actually 4579 persons died from tuberculosis in 1929, whereas in 1919 the figure was 6376.

THE COST OF MEDICAL BENEFIT.

He pointed to the value of improved diagnosis and extended institutional treatment, but said that the amounts expended by approved societies in sickness and disablement benefits were still abnormally high. In 1929 the amount so expended was £1,924,000, or an increase of £200,000 over the corresponding figure for 1928. The severe epidemic of influenza in the early months of 1929 would account for some part of the increased expenditure. But after making allowance for this, and for a slight increase in the number of insured persons at risk last year, there remained a considerable part of the increase for which no satisfactory explanation was available. The department had been in conference with the approved societies and with a special committee of the Insurance Acts subcommittee of the British Medical Association, but it had not hitherto been possible to publish accurate statistical information concerning incapacitating illness among the insured. Now, however, they had put into operation, on July 1st of this year, a scheme for collecting complete and trutsworthy data from the approved societies from which might be compiled statistical records, inter alia, (1) the incidence of the various incapacitating diseases and their duration, not only for insured persons generally, but for groups of insured persons arranged according to area of residence, occupation, age, &c.; and (2) the extent to which individual medical practitioners were granted certificates of incapacity for work. The scheme was considered recently at a conference between the department and representatives of the larger approved societies in Scotland, who promised coöperation. It was hoped that the morbidity statistics, when published, would be of great advantage to the local authorities.

Sir ROBERT HAMILTON said they had recently passed an Act to put the Highlands and Islands Medical Fund on a stable basis. There was no fund of its size which was so well administered, or which did so much good over so large an area. But in looking into the figures he had been disappointed.

HOUSING PROGRESS.

Dealing with the housing question in Scotland Mr. ADAMSON said that up to May 31st, under all forms of State assistance, 110,136 houses, accommodating 495,000 people—a ninth of the working-class population of the country—had been completed, but 100,000 more houses were required. The average reduction in cost under falling prices was estimated at £75 per house, and the new county councils in Scotland had been urged to see that the utmost advantage was taken by rural owners of the Housing (Rural Workers) Act, 1926. He looked forward to activity from the local authorities when the Slum Clearance Bill became law.

Sir JOHN GILMOUR referred to his personal responsibility for the changes now taking place, for which he said no claim was made that they were unalterable. There was now an opportunity for coördination and linking the health of the child from earliest years through school-days and from school-days onward. If the health of the child only were assisted by the new coördination the Act would be justified. There was an obligation now on Parliament to set aside year by year whatever sum might be necessary for carrying out health services in the north of Scotland in addition to the £42,000 provided under the 1913 Act. There was a total of £72,000 provided in the present estimates. Last year £74,800 was available, and with the extension of the services he found the provision insufficient. He hoped the Government were not intending to contract the finances of the fund, but were rather looking forward to its expansion. The extension of the nursing services in the country districts in the north of Scotland had been invaluable. But the difficulty of the nurses getting about was very considerable, and he was glad that the department proposed that in future they should be supplied with light cars. Another direction in which very useful work had been done by the fund was in helping to build doctor's houses. But there were one or two cases where delay had taken place in this respect. He called particular attention to the case of the island of Whalsay, in the Orkneys, where a doctor's house was not yet built, and the doctor on the island had been living in most uncomfortable conditions. Another piece of useful work which the department had done was in putting doctors' houses on the telephone. The department had subscribed the money and had thus got over the parsimony of the post-office in the interests of humanity. The department should insist that every doctor in a country parish where there was a telephone service should be put upon the telephone. Referring to the position of the hospital in Lerwick, Sir R. HAMILTON said a considerable sum was raised annually—as much as the poverty of the people would allow—in order to enable that hospital to keep going. But since the Government department had given the services of a consulting surgeon the hospital had become almost full of surgical cases, and there was practically no room for ordinary medical cases. All the surgical cases which used to go to Aberdeen and Edinburgh were now being dealt with locally. He wished to ask the Secretary of State for Scotland whether it was possible to make a grant from the fund for the extension of a local country hospital which was doing such magnificent work.

Mr. MCGOVERN urged that the Secretary for Scotland should at the earliest possible moment call a conference of all public assistance committees in Scotland with a view to dealing with the totally inadequate scales of relief to unemployed workers.

Mr. MACQUISTEN suggested that there were in the Highlands a great many manses, and while it appeared difficult to get the lad of parts to go in for the Church, it occurred to him that there might be a combination in many of the districts of the Highlands of the clergyman and the doctor, with the manses as residences.

Mr. MACPHERSON said he wished to plead for the class of hospital such as the Invergordon Hospital—a sanatorium hospital. He was anxious that the good work started locally by local authorities should be assisted where necessary by the Government. The hospital at Invergordon was exceedingly well managed, and he could say the same about every other hospital of that class. There were the Ross Memorial Hospital at Dingwall and the Northern Infirmary at Inverness. They had established under the ægis of the Department of Health a specialised service of highly skilled consultants and surgeons. By developing the hospital system in the north of Scotland they were easing the burden of the hospitals in the south, and benefiting not only the local community but the community as a whole. He hoped that they would have an assurance from the Government that they would not only maintain the grant of £72,000 for the Highlands and Islands Medical Service, but if need arose they would persuade the Chancellor of the Exchequer to add to the guarantee.

Mr. HARDIE, referring to Mr. Macquisten's suggestion, said that if a man was fit for medical work he must concentrate on medical science, whereas if he was fit as a spiritual adviser he must confine himself to spiritual subjects.

Mr. R. W. SMITH said he hoped the Government would see that school teachers considered it part of their duty to see that school-children were clean and tidy, ensuring thus that mothers would be more willing to visit the maternity welfare centres.

Mr. RAMSAY said that the question of the delegation of health services to the island of Lewis had caused something like a deadlock for a considerable time. The county councils of Inverness and Argyll had delegated the health service to a specific committee belonging more or less to the islands of these two counties, but unfortunately the people of Lewis had not received a similar delegation. He hoped that the Under Secretary would give them an assurance that something would be done in this respect, because it was a serious thing from the health point of view in Lewis. The late Government and the present Government had done splendid work for Lewis in establishing the Lewis Hospital, but he wished that provision were made for more ambulances and stretchers. A recent case was brought to his notice of a man suffering from peritonitis who died, largely because no near ambulance or stretcher was available to take him to hospital.

Mr. LOVAT-FRASER called attention to the dental service in the Highlands and Islands, and urged that further provision should be made in that respect.

Major ELLIOT, referring to the general improvement of public health in Scotland and especially to tuberculosis figures, pointed out that, while water-borne diseases had been practically conquered and food diseases were in the way of being conquered, air-borne diseases were still completely unsubdued. He referred to the incidence of epidemics among crowded and tenement populations, and pointed out that, taking pre-school children into account, bronchopneumonia, measles, and tuberculosis accounted for 57 per cent. of the deaths. To clean up the air would take a long time, but lung diseases especially were a sign of lowered resistance. While other figures showed that the fundamental resistance of the race was not being safeguarded, attention would give the best results if focused on the child. If they had not a sound child between the ages of 1 and 5, it was useless to try to pump education into such a child between 14 and 16. The report to the department spoke of defective vision as the greatest difficulty in the matter of the school-child. As a sufferer from defective vision, he was quite sure that rheumatism, toothache, or anæmia constituted the greater prejudice to the absorption of knowledge. Scotland, it appeared, had turned largely towards preserved foods, and the necessity of studying these products scientifically stood out. During the last ten years the poor-law authorities had spent ten millions on the purchase of food for the poor-law population of Scotland without any examination of the principles governing dietetics. He referred to the physiological value of the generally rough food on which our ancestors lived.

Mr. JOHNSTON (Under Secretary of State for Scotland), replying to the debate, said it was far too early to say how the new Local Government Act was being fitted into the machinery of local government in Scotland. The machinery creaked a little here and there. It creaked rather badly in Lewis, and they had considerable difficulty in fitting in the desire of the people for local government and financial autonomy, with considerable State subventions, with the control which was being exercised by the county council of which it formed a part. But it was fair to say that the Act was working with considerable facility and smoothness taking the country as a whole. With regard to St. Kilda, the evacuation of which had been discussed, the Government would take every possible step to see that the people were accommodated in future in better surroundings. The poverty under which they had lived was almost indescribable, and they were faced with famine. Had it not been for the Queen's nurse, who stayed in the island during the last two winters, Heaven knew what tragedies would have occurred. He could assure Sir R. Hamilton that the department had every sympathy with the point of view he had expressed, and they were not at all desirous of cutting down the expenditure in respect of the Highlands and Islands Medical Fund. They proposed to assist telephones in the rural areas. The Secretary of State and he had been giving the question of calling a conference of public assistance committees to discuss the equalisation of the present scales of relief, particularly so far as they applied to children, very serious consideration. He would not follow Mr. Macquisten in his irrelevant but rather humorous dissertation upon medical missionaries among the aborigines of the West Highlands. They were sending inspectors to local authorities, and doing everything in their power to induce them to make the maximum effort to improve rural housing in Scotland. He agreed with Major Elliot that they were making very considerable progress in public health, not only in regard to tuberculosis, but along other lines. They were making some progress in regard to nutrition, and if their milk experiment succeeded they would make a great advance in that direction. They were also making progress in regard to fresh air. There was nothing which the Secretary of State was conscious of having left undone in the new Housing Bill to wipe away the slums in Scotland, and to secure a healthier environment for the next generation.

The vote was agreed to.

THE HOUSING (SCOTLAND) BILL.

The Housing (Scotland) Bill was considered on report in the House of Commons on Tuesday, July 15th.

On the motion for the third reading of the Bill

Mr. ADAMSON (Secretary of State for Scotland) said the discussions had shown that in its main structure the measure was generally acceptable to the House and also to the local authorities. A number of suggestions had been put forward from all sides of the House for its improvement, and the Government had met to a very large extent the representations of members of the opposition. The Bill, in the main, however, so far as the procedure for

dealing with slum areas and individuals in insanitary houses were concerned, remained substantially unaltered. He was satisfied that the terms of the new grant were much more favourable to the local authorities than the present grant, and that in practice it would be found that the terms were exceedingly generous. They had been so designed as to offer the greatest inducement to local authorities to erect the larger sized houses which were so badly needed in Scotland for the rehousing of families. He appealed to the local authorities that they should at once proceed actively to put their powers into operation, and wipe away the reproach which had so long rested on Scottish housing.

Major ELLIOT said that it was not possible for Scotland to call itself civilised so long as children were kept awake by vermin, or walls were allowed to be built in front of windows so that it was not possible to see the light of day, and people had to burn gas throughout the 24 hours. But these great evils could not be remedied by State action alone. In many ways the housing conditions in England were an example to Scotland. What was improving and saving the situation in England was the great programme of unassisted houses which was being carried out south of the Border, and unless Scotland could get this assistance into her housing problem it would lag behind England in reaching a solution.

Dr. FORGAN congratulated the Government on producing in this Bill easily the best measure of the present Parliament. The simplification of machinery would enable local authorities, should they so wish, to proceed at a more rapid rate with the demolition of slums and with an attempt to deal with overcrowding. Overcrowding in Scotland was incomparably worse than in England. There were 98 per cent. of those living more than four in a room who were living in either one or two-roomed houses; of those living more than three in a room, 90 per cent. were housed in either one- or two-roomed houses; and of those living more than two in a room 77 per cent. were in one- or two-roomed houses. This Bill compelled local authorities to face the facts of the situation. There was to be a survey at once, and then another three years hence, and subsequently one every five years. In the past local authorities had been content to rely on old statistics. The more stringent the local authority made its standard of housing the bigger the grant which it would be able to earn in an improvement area.

After further debate,

The Bill was read a third time.

In the House of Lords on Tuesday, July 22nd, the Housing (Scotland) Bill, which has passed through the House of Commons, was read a second time. On the same day the Commons amendment to the Workmen's Compensation (Silicosis and Asbestos) Bill was agreed to.

INSURED PERSONS AND OPHTHALMIC BENEFIT.

On Tuesday, July 15th, in the House of Commons, Mr. WOMERSLEY moved "That an humble Address be presented to His Majesty praying that Regulation 25 of the National Health Insurance (Additional Benefits) Regulations, 1930, dated 18th June, 1930, be annulled." The portion of the regulation to which he raised objection read as follows:—

"Where a member has submitted himself to the examination of a medical practitioner under the scheme of a body or organisation which provides both ophthalmic examination and optical appliances, he shall not be entitled to obtain the appliance prescribed by such practitioner from an optician who is not associated with that body or organisation."

Under the present arrangements, the hon. Member continued, there was a body of qualified opticians known as the Joint Council of Qualified Opticians. They had been prescribing for some considerable time for members of approved societies, and the arrangement had worked very satisfactorily indeed. Now, however, the ophthalmic surgeons had set up the National Ophthalmic Treatment Board, and they had taken on to that Board certain firms who supplied optical glasses, with a request to the Ministry of Health that special privileges should be given to the Board. The speaker went on to say that although the fees under the new arrangement had been lowered, the number of opticians was insufficient, and, as there was no complaint against the previous methods of carrying on the work, the approved societies wanted to know the reasons for the change.

Mr. BIRD, in seconding the motion, spoke generally of the position of those who had passed the examination of the British Optical Association or that instituted by the Company of Spectacle Makers.

Mr. GREENWOOD (Minister of Health) said that arrangements for additional benefit must be dealt with by the Regulations, which were formulated after full consultation with the Approved Societies Consultative Council of the Ministry. He was not concerned with differences of opinion between the medical profession and the Joint Council, save that he would hold the balance as fairly as he could. Any approved society would be free to make its normal arrangements if it was providing ophthalmic treatment directly with a representative body of opticians, and in the vast majority of cases that was the course which would be followed. The leading organisation of opticians was the Joint Council of Qualified Opticians. The British Medical Association had made two alternative schemes with a view to making it possible for societies to get advice from ophthalmic surgeons with a minimum of cost. In the first scheme they had prepared a list of medical practitioners who had experience of dealing with ophthalmic cases and were willing to test the sight of insured persons and prescribe glasses. Under this scheme the insured person, having got his prescription, could go to any qualified optician throughout the country. The second scheme was a combined one, and was an arrangement between the medical profession on the one hand and a body not representing a large number of firms, the Association of Dispensing Opticians, on the other hand; firms, he imagined, to which most members of the House of Commons went when they had their prescriptions made up. They were people who never prescribed, but always made up prescriptions from ophthalmic surgeons. Under that combined scheme it was quite clear they could not have that free choice of opticians which they had under other schemes. But the insured person need not adopt this scheme unless he wanted to. There was no hardship in that. He was not prepared to accept entirely the medical view, or the view of the Joint Council. While there might be many cases which might be attended to by the Joint Council there might be many other cases where skilled advice was imperative, but the two bodies would meet everybody's needs. He hoped the House would not be so ill-advised as not to permit these Regulations to go through, but would allow them to pass as provisional Regulations designed for the benefit of insured persons.

Mr. RHYS DAVIES protested against the limit of choice given to the insured in the matter of ophthalmic treatment, but Dr. MORRIS-JONES said that if the Regulation were deleted it would take away what opportunity for choice there was; and after further discussion the motion for an address praying that the Regulations should be annulled the motion was rejected by 144 votes to 23.

WORKMEN'S COMPENSATION (SILICOSIS) BILL

On the motion for the third reading of the Workmen's Compensation (Silicosis) Bill, in the House of Commons on July 15th,

Dr. VERNON DAVIES said that many men who had been in the industry for 15 or 20 years would show on examination signs of silicosis, and in that case employers might use that as a means of dismissing them in order to avoid future compensation.

If a workman was compulsorily suspended before he became disabled would he be entitled to compensation?

After further debate,

Mr. SHORT (Under Secretary to the Home Office) said that so far as he was aware there had been no complaint in connexion with the various schemes in operation respecting dismissals from the causes indicated by Dr. Davies. At the same time it was possible under Section 47 of the Workmen's Compensation Act to cover the two points.

The Bill was read a third time.

HOUSE OF LORDS.

THE SLUM CLEARANCE BILL.

On Monday, July 21st, The Housing (No. 2) Bill passed through Committee.

HOUSE OF COMMONS.

THURSDAY, JULY 16TH.

Unhealthy Labour Conditions in East London.

Major NATHAN asked the Minister of Labour whether she was now in a position to make a statement regarding the sweated wages and unhealthy conditions of labour among many out-workers in East London, and particularly in the boot and shoe industry.—Miss BONDFIELD replied: The inquiries by my Department with regard to wages in the boot and shoe trade in East London are still in progress, and will not be completed for some time. The question of unhealthy conditions of labour is one for the Home Office.

Sale of Poisonous Drugs from Automatic Machines.

Dr. MORRIS-JONES asked the Home Secretary whether he was aware that drugs of a poisonous character could be procured from automatic machines outside chemists' establishments in the county of London; and whether, in view of the Poisons and Pharmacy Act, 1908, and the danger involved to the public, he would cause such vendors to be prosecuted.—Mr. CLYNES replied: I have seen in the press the report of a case in which the legality of such sales was raised, and the Judge decided that they involved a breach of Section 3 of the Poisons and Pharmacy Act, 1908. The proceedings for the recovery of a penalty under that section are of a civil character, and are instituted by the Registrar of the Pharmaceutical Society, and I have no power to intervene. I understand the case in question was arranged by the Pharmaceutical Society for the purpose of testing the legality of such sales, and the judgment will, no doubt, be taken note of by those concerned.

Street Accidents to Policemen in London.

Mr. HACKING asked the Home Secretary the number of police officers engaged on regulation traffic in the Metropolitan police area who had been either killed or injured during the past 12 months; and whether all officers engaged upon this duty are compelled to wear white sleeves.—Mr. CLYNES replied: 171 officers were injured, none fatally. Officers engaged on this duty are required to wear the white gauntlets provided, but it occasionally happens that an officer has to take up traffic duty at short notice without gauntlets.

Malnutrition among School-children.

Mr. MCSHANE asked the President of the Board of Education if he would institute comparative medical examinations of representative samples of school-children, of men who had been for some time unemployed, and of men belonging to the regularly employed artisan class.—Sir CHARLES TREVELYAN replied: Apart from the practical difficulties involved I doubt whether the investigation suggested would lead to any useful results. I may, however, point out that it is the duty of local education authorities, as part of the ordinary work of the school medical service, to discover whether children are suffering from malnutrition, and that in areas where industrial depression is acute special steps are taken to keep a close watch on the health of the children, and to provide supplementary nourishment in cases of need.

Poison Gas Experiments on Living Animals.

Mr. FREEMAN asked the Secretary of State for War whether he had any evidence showing that poison gas and other experiments on living animals being conducted at Porton threw any light on the effects of such poisons on human beings.—Mr. T. SHAW replied: The results which have been obtained both during and since the Great War show that experiments on animals at Porton give definite evidence of the mode of action of poison gases on human beings. Indications are also obtained of the curative treatment which should be adopted, and I am advised that the knowledge thus gained resulted in great alleviation of human suffering during the Great War.

Medical Attention for Families of Naval Men.

Mr. HORE-BELISHA asked the First Lord of the Admiralty what arrangements were in force for providing medical attention for the families of officers and men in the Navy.—Mr. AMMON (Parliamentary Secretary to the Admiralty) replied: The families of officers and men in the Navy are not entitled to medical attention at the public expense. As a privilege, however, the families of Naval personnel serving in particular appointments in certain shore establishments and the families of Royal Marines resident in barracks are afforded free medical treatment by the medical officer of the establishment subject to certain conditions, one of which is that no extra expense to Navy Votes is thereby entailed. As an exceptional measure, a contribution from Naval Funds is also made in approved cases towards the cost of the treatment afforded, either in the Military Hospital or in the King George V Merchant Seamen's Hospital, Malta, to the British wives and families of ratings who, having joined the Navy in the United Kingdom, are temporarily resident at Malta while serving on the Mediterranean Station. Assistance has also been given by means of a grant from the residue of the Naval Prize Fund to enable them to obtain out-patient treatment and medical attention in their own homes at reduced rates. This latter privilege is applicable also to families of Officers.

Tuberculosis in the Navy.

Mr. MARKHAM asked the First Lord of the Admiralty how many stokers or engine-room artificers had been invalided with tuberculosis from the Royal Navy during the past year.—Mr. AMMON replied: The numbers of stokers and engine-room artificers invalided from the Royal Navy on account of pulmonary tuberculosis during the year Jan. 1st–Dec. 31st, 1929, are as follows:—

Chief Stokers ..	2	Chief Engine-room Artificers	4
Stoker Petty Officers	11	Engine-room Artificers ..	11
Leading Stokers ..	10	Engine-room Artificer Apprentices	2
Stokers	35		
	58		17

Deaths from Small-pox.

Mr. BROAD asked the Minister of Health what were the latest figures showing the number of small-pox deaths registered in France, Germany, Italy, Switzerland, Spain, Austria, Norway, Sweden, Denmark, and Russia.—Mr. GREENWOOD replied: According to the official returns received from the countries in question, no deaths from small-pox were registered during the year 1929 in Germany, Switzerland, Austria, Norway, Sweden, or Denmark, while three deaths occurred in Spain. According to the figures published by the Health Section of the League of Nations there were no deaths from small-pox in France during 1929, while five deaths occurred in Italy during 1927, which is the latest year for which information is available in respect of that country. No particulars are available in regard to deaths from small-pox in Russia.

Medical Examination of War Pensioners.

Mr. STEPHEN asked the Minister of Pensions if he was aware that an applicant for increase of pension on the ground of deterioration was not granted a full medical board; under what regulation such claims were considered only by one medical officer; and if he would take steps to see that a full medical board was granted in each case, and that the man's own medical adviser, who was fully conversant with the man's condition, was consulted before a decision was arrived at.—Mr. F. O. ROBERTS replied: Medical examination and certification may, under the terms of the Warrant, be carried out by one or more medical officers, according to the circumstances of the case. The class of case to which my hon. friend refers is one in which examination by an experienced medical officer is normally sufficient, though a specialist or another medical officer may be associated with him where necessary. Opportunity is given, especially where an applicant has been recently under the care of his private practitioner, to furnish any statement from such practitioner, and full consideration is always given to the statement, but it would not be practicable or necessary to adopt the practice suggested by my hon. friend in every case.

MONDAY, JULY 21ST.

Deaths from Small-pox.

Mr. GROVES asked the Minister of Health how many deaths from small-pox occurred in the year 1929; the ages of the cases; and the vaccinal condition of each case.—Mr. GREEN-

WOOD replied: During the 52 weeks ended Dec. 28th, 1929, 39 deaths occurred in England and Wales which were classified to small-pox. The ages and vaccinal condition of these cases are shown in the following table:—

Age.	Vaccinal condition.	Age.	Vaccinal condition.
3 days.	Unvaccinated.	34 years.	One unvaccinated,
14 ,,	,,	(2 cases).	One vaccinated.
3 weeks.	,,	36 years.	One unvaccinated.
(2 cases).		(2 cases).	One vaccinated.
1 mth.	,,	37 years.	Unvaccinated.
2 mths.	,,	42 ,,	Vaccinated.
8 ,,	,,	43 ,,	,,
(2 cases).		44 ,,	Unvaccinated.
16 mths.	,,	45 ,,	Vaccinated.
2 years.	,,	(2 cases).	
9 ,,	,,	59 years.	,,
13 ,,	,,	61 ,,	,,
14 ,,	Vaccinated.	63 ,,	Unvaccinated.
16 ,,	Unvaccinated.	64 ,,	,,
17 ,,	,,	65 ,,	One vaccinated.
20 ,,	Vaccinated.	(2 cases).	One doubtful.
24 ,,	Unvaccinated.	66 years.	No information available.
25 ,,	,,		
28 ,,	Vaccinated.	74 ,,	Doubtful.
29 ,,	,,	75 ,,	Vaccinated.

I may add that all the vaccinated persons had been vaccinated in infancy only and, as the table shows, they were aged 14 years and upwards at the date of death.

Residential Treatment for Tuberculosis.

Mr. DAY asked the Minister of Health the latest available figures of persons undergoing residential treatment for tuberculosis from the local authorities in England and Wales, and the number of persons awaiting admission to sanatoria at the same date.—Mr. GREENWOOD replied: The number of patients receiving residential treatment for tuberculosis under the approved schemes of local authorities in England and Wales on the 1st July, 1930, was 22,575. The number who, on the same date, had been awaiting admission to residential institutions for more than ten days was 3232.

Recruitment for Indian Medical Service.

Major GRAHAM POLE asked the Secretary of State for India what action the Government proposed to take in regard to the resolution passed at the conference of representatives of the provincial governments and the medical faculties convened at Delhi in June, requesting the Secretary of State to change the rules governing recruitment to the Indian Medical Service, so as to remove the provision that only persons holding degrees recognised by the General Medical Council in this country might be selected for the Indian Medical Service.—Mr. WEDGWOOD BENN replied: I have not yet received the Government of India's views.

Lieut.-Colonel FREMANTLE asked Mr. Benn to do everything he could to insist that in any such change of rules there would be no degradation of the service that had done so much and was expected to do so much by keeping its standard up to the European standard.

Mr. BENN: I can make no statement until I have seen the views of the Government of India.

TUESDAY, JULY 22ND.

Poison Gas Experiments with Animals.

Mr. FREEMAN asked the Secretary of State for War what evidence he had, and how it was obtained, that the experiments conducted at Porton of poison gases on animals showed that those gases had the same effects on human beings.—Mr. T. SHAW replied: A comparison of the gross and microscopic appearance of the lungs of men killed by irritant gases in France with those of animals exposed to the same substances showed that the injuries were of similar nature and character, and further study of such animals gave evidence of the mode of action of the poisons and their effects on vital organs. It was thus possible by correlating these experiments with clinical observations on gas patients to formulate curative treatments. Descriptions and results of this research were published in the medical press shortly after the war.

Calmette Prophylactic Treatment.

Mr. FREEMAN asked the Minister of Health whether he was yet in a position to state the result of the inquiries of the representatives of the Medical Research Council into the death of 20 infants in Lübeck, Germany, following the Calmette prophylactic treatment.—Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health) replied: No, Sir. My right hon. friend has no information at present beyond that contained in the answer given to my hon. friend on the 8th instant.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JULY 12TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 138 (last week 156); scarlet fever, 1776; diphtheria, 1287; enteric fever, 85; pneumonia, 533; puerperal fever, 39; puerperal pyrexia, 86; cerebro-spinal fever, 13; acute poliomyelitis, 11; acute polioencephalitis, 3; encephalitis lethargica, 16; dysentery, 8; and ophthalmia neonatorum, 107. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on July 15th–16th was as follows: Small-pox, 229 under treatment, 4 under observation (last week 281 and 11 respectively); scarlet fever, 1773; diphtheria, 2003; enteric fever, 32; measles, 326; whooping-cough, 75; puerperal fever, 27 (plus 13 babies); encephalitis lethargica, 121; "other diseases," 19. At St. Margaret's Hospital there were 13 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there were no deaths from small-pox, 1 (0) from enteric fever, 18 (5) from measles, 7 (0) from scarlet fever, 11 (4) from whooping-cough, 27 (3) from diphtheria, 44 (12) from diarrhœa and enteritis under two years, and 16 (1) from influenza. The figures in parentheses are those for London itself.

Five fatal cases of diarrhœa were reported from Birmingham, 4 from Liverpool, and 3 from Hull.

The number of stillbirths notified during the week was 272 (corresponding to a rate of 38 per 1000 births), including 51 in London.

INDEX TO "THE LANCET," VOL. I., 1930.

THE Index and Title-page to Vol. I., 1930, which was completed with the issue of June 28th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

NEW YORK STATE WOMEN'S HOSPITAL.—Last year this hospital treated 2527 ward patients at a cost of $6·444 per head per day; private room patients cost $7·698 per day. In-patients of both categories reached a total of 5416, and there were 8315 out-patients. The service for the reception of visitors has been greatly improved by the appointment of a hostess. There were 1609 obstetrical cases, and 1342 babies were born, with a maternal mortality of ·87 per cent. and an infant mortality of 2·64 per cent.

OCCUPATIONAL THERAPY FOR MENTAL CASES.—The report for last year of the medical director of the Bloomingdale Hospital, White Plains, New York, shows that of the 224 patients (110 men and 114 women) who were discharged, 59 were fully recovered, 33 much improved, and 62 improved. The average period of treatment of the recovered was 7 months and 21 days, and of those improved 9 months and 29 days. A considerable number of those discharged are kept under observation by means of visits to the hospital, an arrangement which is found to be "of great value in aiding them to complete their adjustments and to seek early advice in the event of the return of any unfavourable symptoms." All patients whose condition permits go to the occupational therapy buildings for regular periods each day. Over 28,000 articles were made or repaired by them, and in addition the printing office turned out 467,000 pieces of printed matter, including a number of pamphlets of value to the medical, nursing, and therapeutic services. "It is found that the actual accomplishment of some worth-while piece of work gives the best results in this form of treatment."

OBITUARY

HENRY FRASER, M.D. Aberd., M.R.C.P. Lond.

Dr. Henry Fraser, who died suddenly on July 17th, while on holiday at Pitlochry, Perthshire, was born in Aberdeen in 1873, and received his preliminary education there. After a brilliant career as a student of medicine in Marischal College, he graduated M.B., Ch.B. from the University of Aberdeen in 1900. He was awarded the Anderson Research Scholarship, and in the two years following graduation studied pathology at Berlin and Halle. On his return to Aberdeen he proceeded to the degree of M.D. and the D.P.H., in 1902.

Fraser's inclination was towards the investigation of disease rather than medical practice. By reason of his training in pharmacology, chemistry, and pathology he was specially well equipped for laboratory research. In 1906 he was chosen by the Colonial Office to succeed C. W. Daniels as Director of the Institute for Medical Research, Federated Malay States. During the ten years he occupied this post, Fraser made a series of valuable contributions to the study of tropical diseases; his researches in beri-beri, bacillary dysentery, and leprosy gained for him an international reputation. On his retirement from the Colonial service in 1916, he served in the Royal Army Medical Corps, first at Malta, and later at Salonica. After the war he was engaged in the Ministry of Pensions service in London and Birmingham as a consultant in tropical diseases. In consequence of impaired health he retired from active work a few years ago, and latterly he lived quietly at Leamington Spa. In 1926 he was admitted M.R.C.P. London.

Fraser was one of a distinguished group of pathologists trained at the University of Aberdeen under the inspiring influence of Prof. Hamilton. His work in the tropics received less in the way of formal recognition than was its due, but his name will be held in high honour by the colleagues who were privileged to be associated with him there. He would, perhaps, desire no other memorial.

HECTOR G. G. MACKENZIE, D.S.O., M.D. Durh.

THE death occurred suddenly on Saturday, July 19th, of Dr. Hector Mackenzie at his flat in West Kensington.

Hector Graham Gordon Mackenzie was educated at Winchester and the universities of Oxford, Edinburgh, and Durham. He graduated in Arts at Oxford in 1897, and at Edinburgh was demonstrator of physiology in Surgeons' Hall. In 1907 he graduated in medicine at the University of Durham, proceeding to the M.D. degree in 1913. His first medical appointments were in connexion with tuberculosis, and he was for a time house physician to the Brompton Consumption Hospital and assistant tuberculosis officer at Charing Cross Hospital. He was known publicly for his deep interest in boys' clubs, and many social workers are aware of the scheme which he projected for the development of medical control in these institutions. His views on the subject were published in a pamphlet entitled "Medical Control in a Boys' Club," while the practical experience which led him to form these views was gained as medical officer to the Hollington Boys' Club, with which he was connected for many years; he was also honorary medical officer to the Secondary Schools Camp Association. He was deeply attracted by the problems allied to medicine which arise out of the study of many aspects of mental healing, and wrote on this subject generally, and also on the influence of treatment at Lourdes.

During the war Dr. Hector Mackenzie was very active on more than one front in ambulance service, and attained the rank of Lieut.-Colonel R.A.M.C. He was widely known to a large circle of patients and friends, and, as will be gathered from this brief record, possessed a fertile mind and an enthusiasm for social causes.

PHILIP BRUNELLSCHI COUSLAND, M.B. Edin.

Dr. P. B. Cousland, who died in British Columbia on July 7th, was for many years editorial secretary of the Chinese Medical Translation Committee, and took an important part in the development of western medicine in China. Born at Glasgow in 1861, the son of James Cousland, he was educated at George Watson's College, Edinburgh, and Edinburgh University. After being house physician at Leith Hospital he went out to China, under the Presbyterian Church of England and the China Medical Missionary Association, to Swatow Hospital, in 1883. Three years later he transferred to Chaochowfu, where until 1906 he engaged in medical, evangelistic, and other work, including a great deal of translation. He then moved to Shanghai, his services being lent to the China Medical Missionary Association (now the China Medical Association) for the purpose of editing, translating, and publishing medical books in Chinese. He was President of the Association from 1910 to 1913.

"It was in 1890," writes a correspondent, "that Dr. Cousland became a member of the terminology committee of the Association, and the bulk of its work fell upon his shoulders. It largely lay with him to render in Chinese ideas and words wholly foreign to the Chinese language. The ideographs had each to be considered separately by the committee, before they were adopted or improved, and finally used in the work of the translation of foreign medical works in Chinese. The Chinese Government eventually itself took part in this task, and appointed a special committee to deal with the matter, on which the Medical Missionary Committee was represented. He was himself the author of 'English-Chinese Medical Lexicon,' and he translated Osler's 'Practice of Medicine,' Halliburton's 'Physiology,' and Younger's 'Insanity in Everyday Practice.'"

Dr. Cousland was twice married, first to Miss Susan Harrington, and secondly to Miss Ida Rebecca Luther. He retired from active work some years ago and settled at Victoria, B.C., where his younger son is in medical practice.

WORCESTER GENERAL INFIRMARY.—During 1892 there were 1941 admissions, an increase of 160, and the average stay was 19·7 days. New out-patients numbered 5983 (casualties 3366), an increase of 628. The average total cost of each in-patient was £6 11*s.* 11¼*d.*, an increase of 8*s.* 5*d.* upon the previous year, and the cost per occupied bed was £129 4*s.* 10½*d.*, an increase of £12 2*s.* 10½*d.* In its second year the contributory scheme produced slightly more than £9000; the county membership is 11,000, and the Worcester city membership 14,000. It has been decided to raise the number of beds from 118 to 150, with a further increase to 200 as means become available.

MEDICAL NEWS

University of London.

At a meeting of the Senate on July 16th Dr. Samson Wright was appointed to the university chair of physiology at Middlesex Hospital Medical School.

Dr. Wright was formerly a student of this school and qualified in 1920. He graduated as M.D. Lond., and became a Member of the Royal College of Physicians in 1925. At the Middlesex Hospital, besides holding clinical appointments, he was formerly senior demonstrator of physiology, but since last autumn he has been lecturer in physiology at King's College. His original work has followed several branches of applied physiology and his text-book on this subject is familiar to advanced students.

The title of Professor was conferred on Dr. J. G. Thomson (Medical Protozoology), and Dr. G. S. Wilson (Bacteriology as applied to Hygiene), in respect of their posts at the London School of Hygiene and Tropical Medicine.

Mr. Alexander Robertson, Ph.D. Glasg., was appointed to the university readership in biochemistry, tenable at the London School of Hygiene and Tropical Medicine.

It was resolved to institute a university chair of radiology, tenable at the Cancer Hospital, Fulham-road, S.W.

The degree of D.Sc. has been conferred on Mr. R. K. Cannan and Mr. S. A. Mann (Biochemistry) and on Miss May Smith (Industrial Psychology).

The Senate have resolved to institute a Diploma in the Theory and Practice of Physical Education.

University of Edinburgh.

At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR M.B., CH.B.

N. J. Abbensetts, A. Amdor, A. J. Bain, B. Berger, James Black, D. M. Blair, A. B. Brereton, A. Brookner, G. J. F. Caley, A. C. P. Campbell, M. Chamurich, D. S. Clark, P. de Beer Clark, W. S. M. Craig, S. Davidson, J. S. de S. Drummond, E. H. Duff, S. Eisenhammer, W. R. de Faria, M. H. Finkelstein, G. S. Forrester, A. K. Fraser, E. M. Fraser, P. Fraser, D. N. Gibbs, J. C. Gibson, J. J. Glover, F. G. Goulder, M. C. Gray, James Guthrie, J. A. Guy, S. Harwitz, A. G. Hill, C. H. Howat, G. J. Hugo, J. L. Hunter, J. C. A. Hunter, E. R. Jamieson, J. M. Jamieson, T. T. Jardine, J. S. Jeffrey, H. M. Johnston, R. Y. Keers, P. L. Lai-Fook, J. S. Lawrence, E. Lazarus, E. Seng Lee, M. J. Leiserowitz, M. A. Lockie, J. M. MacAlister, A. L. Macdonald, A. Macdonald, C. R. Macdonald, S. A. Macdonald, John Mackenzie, A. F. Mackenzie, C. Mackie, A. W. Mackinnon, J. M. MacLennan, P. A. Macleod, K. J. E. MacMillan, W. M. Martin, A. E. Milne, J. M. Modak, I. C. Monro, W. I. C. Morris, H. L. Morrison, I. H. C. Morton, R. B. Nelson, H. J. Newlands, J. A. Noble, J. M. Officer, D. Orr, H. O. Parkinson, M. E. Paterson, J. P. Pennybacker, H. A. Raeburn, P. L. J. C. Ransome-Wallis, R. A. Read, R. L. Renwick, A. N. Roxburgh, U. Schutzer, H. G. Scott Kerr, W. C. Service, T. I. Sibbald, I. H. Silverstein, D. W. G. Smith, C. N. T. Spowart, D. G. A. Stewart, H. Stewart, J. L. Swanston, A. Thomson, T. B. Tibbetts, J. S. Tough, G. Turner, R. E. Verney, L. S. Wakefield, E. S. Walker, R. Walmsley, George Watt, E. J. Welford, A. D. Wilson, T. T. B. Wood, and J. Yunibandhu.

Royal College of Surgeons of Edinburgh.

At a meeting of the College on July 22nd, with Dr. James Haig Ferguson, the President, in the chair, the following 22 successful candidates (out of 73 entered) who passed the requisite examinations between March 27th and April 4th, were admitted as Fellows:—

Mahmoud Ismail Ashmawi, Percy Charles Edward Brunette, Conal Charleson, Arthur Charles Copley, Arthur Brython-Davies, James Dick, Colin Archibald Ferguson, James Paton Galloway, Douglas Medlicott Gibson, Thomas Jordan Gibson, Austen Henry Holmes, John Black Hutchison, Calverley Middlemiss Jennings, Lekhraj Rochiram Lalwani, Alistair Campbell McEachern, Hamish Falconer Masson, John Wright Nankivell, Harold Keith Pavy, William Bernard Roantree, Eric Thomas Sutherland Rudd, Peter Dewar Thomson, and Alister Laird Young.

The Ivison Macadam memorial prize, consisting of a bronze medal and a set of books, was, after a competitive examination in organic chemistry, awarded to Mr. Eng Tay Oon.

Royal College of Physicians of Edinburgh.

A quarterly meeting of the College was held on July 15th, with Sir Norman Walker, the President, in the chair. Lieut.-Colonel W. F. Harvey and Dr. Arthur Oliver Gray were introduced and took their seats as Fellows. Dr. H. L. Wallace (Edinburgh), Dr. William Brown (Aberdeen), and Dr. H. E. Whittingham (Halton, Bucks) were elected to the Fellowship.

It was announced that Dr. D. K. Henderson, of Glasgow, had been appointed Morison lecturer for 1931.

Ulster Medical Society.

The following office bearers have been elected for the session 1930–31: President: Mr. Henry Hanna. Vice-Presidents: Prof. C. G. Lowry, Dr. Craig (Bangor). Secretary: Dr. J. A. Smyth. Assistant Secretary: Dr. F. P. Montgomery. Treasurer: Dr. F. M. B. Allen, Librarian: Dr. S. Simms.

A Course in Surgical Tuberculosis.

Under the direction of Dr. Etienne Sorrel a course in surgical tuberculosis and orthopædics will be held at the Hôpital Maritime de Berck Plage, Pas-de-Calais, from August 4th to 16th. Particulars may be had from Dr. Delahaye at the hospital.

Ross Institute and Hospital for Tropical Diseases.

A meeting was held at the institute on July 9th, when the annual report and accounts of the institute for 1929 were presented (see THE LANCET, May 3rd, 1930, p. 976). Sir Charles McLeod, who presided at the meeting, said that the institute had made substantial progress during the past year under the general direction of Sir Ronald Ross, who spent all his time there. The institute had become known as a prominent centre of research in the field of fungi and fungal diseases. The malaria department had helped both doctors and laymen with advice on antimalarial work, and visits had been paid by members of the institute to Rhodesia and South Africa. An important development since the annual report was published was the opening of a branch of the Ross Institute in Assam to carry out scientific and practical work on the prevention of malaria in Assam and parts of Bengal. Dr. G. C. Ramsay had been appointed director of this institute, and certain firms connected with local industries had agreed to finance it for three years. Dr. R. Mhatre expressed appreciation of the facilities given to visiting doctors to work at the Ross Institute.

Eleventh International Veterinary Congress.

This congress will be held at the Central Hall, Westminster, London, S.W., from August 4th to 9th. The official programme has now been issued. Twenty-six countries will be represented, and the discussions will cover a wide range. General meetings will be held in the mornings and will include discussions on foot-and-mouth disease, tuberculosis, infectious abortion, the relationship of the veterinary surgeon to animal husbandry, veterinary science in relation to public health, and the law governing the practice of veterinary medicine and surgery. In the afternoons sectional meetings will be held on variola in domestic animals; the use of drugs in the treatment of diseases caused by worms; theileriases; fowl typhoid and bacillary white diarrhœa; anthrax; swine fever; milk fever; fowl-pox; genetics; rabies; standardisation of biological products; acute infectious mastitis; control of trypanosomiases; deficiency diseases; black-leg; scientific feeding of animals; distemper; bovine sterility; rinderpest; treatment of parasitic diseases; diseases of the new-born; and fowl plague. Besides the scientific meetings a full programme of social functions has been arranged, and the delegates will be entertained by H.M. Government and by the Corporation of the City of London.

London School of Hygiene and Tropical Medicine.

A reception was given by the School at its new buildings in Gower-street on Friday, July 18th, to welcome members of the Colonial Office Conference. The guests were received in the library of the building by the chairman of the board of management, Sir Harry Goschen, and Lady Goschen, by the chairman of the court of governors, Sir Holburt Waring, and Lady Waring, by the vice-chancellor of the University of London, Sir Gregory Foster, and by the Dean, Prof. W. W. Jameson, in the absence of Sir Andrew Balfour, who was unable to be present. H.R.H. Prince George was among the guests. A series of scientific exhibits was shown in the library by members of the staff of the School; there were technical demonstrations in the various laboratories; and an interesting lecture was given to a large group of the guests by Dr. P. A. Buxton on the modern developments of medical entomology. Other guests had an opportunity to see a fine cinema display in the main theatre, illustrating scenes from primeval life, the emergence of man as leader though pitted against formidable monsters, the fight to-day of man against a myriad of microscopical foes; and school life at the special schools of the Leyton Urban District Council. A large number of guests enjoyed the hospitality of the School.

University of Liverpool.

Dr. W. J. Dilling has been appointed professor of pharmacology.

Hospital Sunday.

Up to July 19th the amount received from the collections on London Hospital Sunday was £68,000.

World League for Sexual Reform.

The fourth congress of the World League for Sexual Reform on a Scientific Basis will be held in Vienna from Sept. 13th to 20th. The address of the organising committee is Postfach 63, Vienna I/15.

A Course on Radium.

Under the auspices of the University of Birmingham a post-graduate Course on Radium Therapy will be held at the General Hospital, Birmingham, from Sept. 22nd to Oct. 4th. Particulars will be found in our advertisement columns.

Harton Poor-law Institution.

The Ministry of Health recently held a local inquiry into complaints concerning the administration of this institution which now belongs to South Shields town council. In stating his findings the Minister says that the evidence suggested that there has been a certain laxity in administration, that no one in the hospital appeared to be definitely responsible for summoning a doctor to the receiving wards, and there was no visible indications there that a doctor was available and on duty. His general conclusion is that there is need for closer supervision.

Royal National Orthopædic Hospital.

Last year 354 in-patients were admitted, and their average stay was 275 days; their average weekly cost was £2 2*s*. 11*d*., with a total per head of £84 3*s*. 11*d*. In addition, 9253 out-patients were treated. The number of patients exceeded all previous totals, and further clinics have been established in various parts of the country in coöperation with the local authorities.

Dumping of London Refuse.

On July 17th Miss Susan Lawrence, Parliamentary Secretary to the Ministry of Health, received a deputation from Essex riverside local authorities affected by dumping of refuse from Greater London.

Mr. H. T. Muggeridge, M.P., spoke of the danger to health inherent in the present practice of forming huge, unsightly, and insanitary dumps in the areas bordering on London. An inter-party committee of Members of Parliament had been formed to press for immediate action. This committee welcomed the recommendation of the Departmental Committee on London Cleansing that there should be a central responsible body, but regretted that continuance of the present method of dumping was contemplated. If, however, dumping in some form must continue, then local authorities should have the right to veto the sites proposed, subject to appeal to the Minister. Mr. F. J. Cole, chairman of Hornchurch Urban District Council, said that the dumps fostered the breeding of rats and flies, and were a grave menace to the public health. The local authorities had little or no control over them. They wished to press for legislation prohibiting further dumping except with permission, and under the control, of the local authorities in the districts affected, any cost incurred by this supervision to be borne by the dumping authority or its contractors. The position had been acute since about 1922 when rapid development of the area began.

Miss Lawrence said she had herself been over one of these dumps, and she thought their existence was a public scandal. But she thought the local authorities had not yet made full use of their existing powers. They could proceed (1) under the nuisance provisions of the Public Health Act, and (2) under the power to make by-laws and obtain continuing penalties for infringement. Hitherto, so far as she was aware, no Essex authority had made by-laws on this subject. Some other areas had done so, and enforcement of the by-laws had resulted in improvement of the conditions. As to legislation, it was not only a question of the merits of the case; there was the very great difficulty that the committee had not been able to agree on the constitution of the central authority. This meant that any legislation was likely to be controversial, and the difficulty of finding Parliamentary time would be correspondingly greater. The Minister proposed to take up with the borough councils the committee's recommendation that dumping authorities should be pressed to discontinue the use of insanitary dumps for their refuse, and take measures to minimise the unsatisfactory conditions. Mr. Oldfield said that procedure by nuisance was useless because it presupposed a dump. Procedure under by-laws was far more promising. It would be more effective if higher penalties were provided, and if the courts had power to prohibit recurrence of the nuisance.

Vacancies

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—McRobert Lecturer in Malignant Disease. £800.
Accrington, Victoria Hospital.—Hon. Anæsthetist.
Altrincham General Hospital, Cheshire.—Sen. H.S., and Jun. H.S. At rate of £150 and £120 respectively.
Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.
Barnsley, Beckett Hospital and Dispensary.—H.P. £140.
Barnstaple, North Devon Infirmary.—Res. M.O. At rate of £150.
Bath, Royal United Hospital.—H.P. and Asst. H.S. Each at rate of £120.
Birmingham, Midland Hospital, Easy-row.—H.S. £200.
Birmingham Univ.—Walter Myers Travelling Studentship. £300.
Brighton, Royal Sussex County Hospital.—Cas. H.S. £120. Hon. Clin. Asst. to the Dermatological Dept. Also Hon. Med. Clin. Asst.
Bristol Royal Hospital for Sick Children and Women, St. Michael's Hill.—H.S. £125.
Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75.
Chester County Mental Hospital.—Jun. Asst. M.O. £350.
Chesterfield and North Derbyshire Royal Hospital.—H.S. At rate of £100-£175.
City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.
Coventry and Warwickshire Hospital.—Two Res. H.S.'s. £150 and £125.
Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £150.
Doncaster Royal Infirmary.—Three H.S.'s and one H.P. All at rate of £200.
Dudley, Guest Hospital and Eye Infirmary.—Asst. H.S. £150.
Eastbourne, Princess Alice Memorial Hospital.—Jun. H.S. At rate of £100.
Evelina Hospital for Children, Southwark, S.E.—H.S. Also Cas. and Out-patient O. Each at rate of £120.
Glasgow Univ.—Samson Gemmell Chair of Medical Pædiatrics.
Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Res. Surg. O. Also H.P. At rate of £175 and £135 respectively.
Grosvenor Hospital for Women, Vincent-square, S.W.—Res. M.O. At rate of £100.
Hertford County Hospital.—H.P. At rate of £150.
Huddersfield Royal Infirmary.—H.S. At rate of £150.
Huntingdon County Hospital.—H.S. £125.
Indian Medical Service.—Commissions.
Kingston-upon-Hull, City and County of.—Res. M.O. for City Hospital, Cottingham. £350.
Leeds Jewish Herzl-Moser Hospital.—Res. M.O. £100.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liverpool Heart Hospital.—H.P. £52.
London School of Hygiene and Tropical Medicine.—Research Studentships in Entomology and Protozoology. Each £250.
Manchester, Ancoats Hospital.—H.P. At rate of £100.
Manchester, City of.—Jun. Res. Asst. M.O. At rate of £275.
Manchester Northern Hospital for Women and Children, Park-place, Cheetham Hill-road.—Hon. Asst. Surgeon for Children.
Manchester Victoria Memorial Jewish Hospital, Cheetham.—Sen H.S. £250. Also Jun. H.S. At rate of £125.
Manitoba University.—Professor and Asst. Professor of Anatomy. $5000 and $3500 respectively.
Margate and District New General Hospital.—Res. M.O. £125.
Middlesbrough, North Ormesby Hospital.—H.P. £120.
Miller General Hospital, Greenwich-road, S.E.—Cas. O. £150.
Newark General Hospital.—Res. H.S. At rate of £175.
Newport, Mon., Royal Gwent Hospital.—Hon. Radiologist.
Queen's Hospital for Children, Hackney-road, E.—Cas. O. £100.
Reading, Battle Hospital.—Asst. Res. M.O. £300.
Rochdale Infirmary and Dispensary.—Jun. H.S. £175.
Royal Northern Hospital, Holloway, N.—Res. Out-patient Cas. O. and Anæsthetist. At rate of £70.
Saint Mark's Hospital for Cancer, Fistula, &c., City-road, E.C.—Res. Surg. O. At rate of £150.
Salford, Hope Hospital.—Res. Surg. O. £400.
Sheffield National Radium Centre.—Medico-Physicist. £600-£800.
Sheffield Royal Hospital.—H.S. to Ear, Nose and Throat Dept. Also Res. Anæsthetist. Each at rate of £80.
Sheffield Royal Infirmary.—H.S. At rate of £80.
Shrewsbury, Royal Salop Infirmary.—Res. H.S. At rate of £160.
Southampton Borough Hospital.—Res. M.O. £350.
Swansea General and Eye Hospital.—Asst. Path. £400–£500.
Taunton and Somerset Hospital.—Jun. H.P. At rate of £100.
Truro, Royal Cornwall Infirmary.—H.S. £170.
Ventnor, Isle of Wight, Royal National Hospital for Consumption and Diseases of Chest.—Asst. Res. M.O. At rate of £300.
Walsall General Hospital.—Cas. H.S. At rate of £120.
Weir Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £150.
West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Jun. H.P. At rate of £100.
Wigan Royal Infirmary.—H.S. At rate of £150.
Willesden General Hospital, N.W.—Jun. H.S. £175. Also Registrars.
Windsor, King Edward VII. Hospital.—H.S. At rate of £100.
Wolverhampton Royal Hospital.—Cas. O., and Res. Anæsthetist. At rate of £125.
Wrexham and East Denbighshire War Memorial Hospital.—Res. H.S. At rate of £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Linslade (Buckinghamshire), Stockton-on-Tees (Co. Durham) Wainfleet (Lincolnshire).

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workman's Compensation Act for the Districts of the Middlesbrough, Stockton-on-Tees, Stokesley, and Guisborough County Courts (Circuit No. 2). Applications should reach the Private Secretary, Home Office, Whitehall, London, not later than August 9th.

NOTES, COMMENTS, AND ABSTRACTS

THE EXHAUSTED CHILD.*

BY RICHARD C. CLARKE, O.B.E., M.B. BRIST., M.R.C.P. LOND.,

HON. PHYSICIAN TO THE BRISTOL ROYAL INFIRMARY AND HON. CONSULTING PHYSICIAN TO THE BRISTOL ORTHOPÆDIC HOSPITAL.

EXHAUSTION and its effects on children have been occupying my attention for some years, and it is my opinion that the exhausted child is a far commoner phenomenon than it used to be, and that the condition is most insufficiently recognised by our profession, by parents, and those to whom we entrust our children for education and upbringing.

It is a condition which shows well-marked physical signs which depend upon the general muscular atony both of the voluntary and involuntary muscles. The intensity of these signs depend upon the degree of muscular atony, and the signs are found at all stages of development in different cases. The most obvious and dramatic is that stance which is best described as "the child standing over itself." In fact, it maintains its upright position by the bony and ligamentous system rather than by muscle tone (Fig. 1). Other signs are hyperextension of the elbow (Fig. 2), which is best seen if the child is told to stand up with its arm extended. The hand takes up a position of extension of the fingers and flexion of the wrist (Fig. 3), and the scapular wing is prominent. In advanced cases the face is expressionless, though grimacing is not uncommon in slight cases. The abdomen is protuberant and the abdominal wall atonic.

FIG. 1.

Stance of exhaustion.

SYMPTOMS.

The Nervous System.—The nervous system dominates the picture, and Dr. H. C. Cameron in his classic, "The Nervous Child," and his other admirable writings on the subject, defines the stance that I am referring to as occurring only in the nervous child. It is perfectly true that the majority are the active-brained, active-bodied type of child, difficult to manage, wayward with an undue amount of negativism, and that they are emotional and introspective, but this is not true of all of them. My own view is that amyotonia is more a symptom of exhaustion, and that it may be produced by exhaustion in any given child, though the margin of error differs enormously with the individual child. Pyrexia is very common in these children. Some show undue pyrexia in trivial infections, and others run evening temperatures for which no cause can be found.

Cardiovascular System.—The symptoms referable to the cardiovascular system are common and important, and depend on the atony of the autonomic nervous system. They consist of pallor and frequent fainting attacks, symptoms associated in the public mind with anæmia and heart disease. The impulse of the heart beat is often heaving and diffuse, and the rate rapid. Accentuation of the first and second sounds and even systolic murmurs may be present. There is often well-marked sinus arrhythmia and there may be even extrasystoles. A further sign of vasomotor instability is the so-called "orthostatic" albuminuria.

Respiratory System.—Although I know that I differ from some observers, I do not think that this type of child suffers more from catarrh of the respiratory system than do other children.

FIG. 2.

Hyperextension of elbow.

Alimentary System.—Anorexia and capricious appetite are common, but more referable to the nervous system. These children, as has been pointed out by several observers, are specially liable to attacks of vomiting, so-called bilious attacks, which may be so severe as to pass on to true cyclical vomiting, a rare disease in my experience All sorts and types of dyspepsias are common, and a coated shiny tongue is the rule. Constipation, varied by attacks of diarrhœa, is common, and abdominal tenderness—most often over the splenic flexure—is often found.

Genito-urinary System.—I have already referred to the orthostatic albuminuria. Nocturnal enuresis, which is always a neurosis, is very common and sometimes intractable. In one child that I took into hospital for observation the bladder was often found half-way up the abdomen without any symptom or cause.

DIFFERENTIAL DIAGNOSIS.

Subacute Rheumatism.—These children are introspective, and make the most of their aches and pains. What child has not from time to time pains in the limbs? This is frequently mistaken for subacute rheumatism. It is not at all difficult to read into the physical signs indications of chronic rheumatic carditis. Dr. Carey Coombs [1] has called attention to the doubtful case, and although he himself is unlikely to go wrong in the matter, I think he runs the risk of misleading the ordinary practitioner when he says: "An increased area of impulse in itself, without alteration of the sounds commands respect," and he suspects "accentuation of the first sound at the apex or the second sound at the pulmonary base."

FIG. 3.

Extension of fingers.

Dr. Reginald Miller [2] has tried to rope this type of child into the rheumatic net, and seems to regard at

*A paper read before the Bristol Medico-Chirurgical Society.

[1] Brit. Med. Jour., 1930, i., 227. [2] Ibid., p. 230.

any rate a good proportion of them as cases of latent chorea. My view is the opposite; a child who has had chorea is always exhausted, and will conform to this type, but only the smallest proportion of these children are cases of chorea. It is well known and unarguable that rheumatic affections of the heart are very uncommon in the nurtured classes; any public school doctor would bear this out. In a secondary school for middle-class girls, I have examined and re-examined 1767 girls; of these at least 15 per cent. are of the grossly atonic type, and a further 20 per cent. show signs in a lesser degree, yet there have been only seven cases of rheumatic heart, an incidence of 0·4 per cent. This atonic type is lamentably common among the very well-to-do, and some of the worst cases are among the only children of the very rich. If these cases were really rheumatic in origin, surely there would be more rheumatic hearts amongst them.

Alimentary System.—The three favourite diagnoses are mesenteric glands, chronic appendicitis, and intestinal toxæmia. If the patients fall into the hands of the surgeon they seldom get away with their appendix intact, and are lucky if they escape without a pleat in their cæcum, a hitch in their transverse colon, or even a short-circuit in their alimentary tract.

Respiratory System.—The most frequent diagnoses are unhealthy tonsils and mesenteric glands. The latter is a harmless diagnosis, as the surgeon has not yet penetrated into this area, and the usual treatment of rest and hygiene is most beneficial. In the former there is more danger, and the plain man is here in a difficult position. There can be no doubt that an unhealthy tonsil is a danger, and should be removed; but what is a healthy tonsil? The current medical press produces mental confusion, and I do not believe that the ordinary rhinologist would admit that there is such a thing as a healthy tonsil over the age of 5. Enlargement of the tonsillar gland in the anterior triangle of the neck, if it be a test of unhealthy tonsils, is almost universal in children over that age. I am always glad when these children have had their appendix and tonsils out already, as it clears the air considerably.

Some gravitate to the orthopædic department of hospitals and remedial classes in schools, where they are treated with exercises. A great many orthopædic departments have realised the necessity of rest as an adjunct, though some have not. Exercises and re-education to the exhausted child are often just an additional burden.

THE GROUNDS FOR THE EXHAUSTION HYPOTHESIS.

I regard the symptom-complex as being produced only by exhaustion, mental or physical or both, and all treatment should be directed along these lines. The conclusion is the result of my observations in the nursery and in the hospital, of school-children and of parents.

Observations in the Nursery.—Anyone with a nursery will agree that the child who has been over-excited, has had too much pleasure, and is overtired, displays some or all of the symptoms that I have mentioned. Night terrors and nocturnal enuresis can be produced in most children by a game of bears before going to bed. It is a commonplace that after a party the child is difficult to manage, and all the tact is needed to prevent a "scene." Children differ very much, but every child has what is called a breaking-point. If carefully observed round Christmas-time, and after too many parties, a child can be seen to be adopting the typical stance.

In Schools.—In examining the girls of the secondary school, I have invariably noted the position, and recommended early bed, no homework, and a rest in the dinner hour for those with the atonic stance; parties and cinemas are forbidden, and no remedial exercises are done. Where these instructions have been carried out, the improvement has been invariable and sometimes dramatic, but where parents have not coöperated the results have been negligible.

In Hospitals.—I have from time to time admitted the most advanced cases for investigation, and have put them "through it," to find some organic cause for the disorder, invariably with a negative result. Nevertheless considerable improvement has always taken place, the result, no doubt, of physical and mental rest. Recently I have been admitting such cases for the sake of the rest only, with the most satisfactory results.

Parents and Families.—In my experience, the worst cases of exhaustion occur in the only children of anxious parents, and when I have had the opportunity of seeing the family it has been the eldest that stands worst. "The only son of his mother, and she was a widow," is perhaps the most intractable case of all. The sole explanation of the only and eldest child phenomenon is that it is never left alone, it is watched day and night, fussed over, and "brought up"—in the worst sense of the word. The alternative explanation, that only the eldest child is nervous, is improbable on the face of it.

WHY ARE CHILDREN EXHAUSTED?

It must be either that the modern child is more easily exhausted and can stand less than his parents, or that modern methods of upbringing and education are all wrong. The former view was put to me very strongly by the headmaster of a great public school in the course of a conversation, but one must always accept this view with reserve. It has been said by every generation since the Stone Age, and we all suffered from it in our youth. None of us think "that our house physicians and clerks know what it is to work as we did." Of course, the war is a common excuse of parents with this type of child. There can be no doubt that the parents of children of present school age were profoundly affected by the late war, no matter what part they were called upon to play in those stupendous times. Whether this could be a factor or no, I must leave to the expert biologists to argue and decide. I myself have an open mind on the matter, but if it be so it cannot be altered, and it simply means that the second factor, the upbringing and education, needs to be modified. My own opinion is that the blame lies entirely with this second factor. The modern child, from infancy upwards, leads far too strenuous a life. In the nursery it is "infant-welfared" from morning till night, it is surrounded with complicated toys and complicated picture-books designed to overtax its brains. In these days of motor-cars, even the street is an adventure.

In education parents pay the piper and the pedagogue calls the tune. Clifford Allbutt uttered many warnings against the cramming system of schools from the nineties, onwards, and since the war Sir Humphry Rolleston has continued the good work, but these are voices crying in the wilderness. We may take it as a fact that every pedagogue will overwork a child if he or she possibly can. Fortunately, most boys put up a defence, but girls, being more conscientious, are easier victims. Since the war the efficiency, in all schools—elementary, preparatory, secondary, and public—has been increased, and this increased efficiency has done away with the old type of pedagogue who, although he may have taught us nothing, at least rested our brains. May it not be that the nerves of the modern child are being sacrificed to efficiency and competition, though the general standard of education may be immensely higher?

TREATMENT.

The treatment of this condition can be summed up in one word: "rest," mental and physical. Directly the child is observed to be standing badly its burden must be lightened, any gross disease must be treated, tonsils, if really unhealthy, must be removed, errors of refraction must be corrected, and the teeth must be put in order. The whole system of Upbringing with a capital U, must be gone into and modified, and school work adjusted to the child's capacity. Early bed, midday rests, no parties or cinemas in term time, and as quiet a life as possible are all obvious precautions. Some of these measures may lead to

clashes with parents or pedagogue, but they must be insisted upon. In a really bad case I start the treatment with confinement to bed for a month. Much has been written by Dr. Cameron and his co-workers at Guy's lately with reference to diet; suffice it to say that these children take fats badly, and that eggs, cream, and cod-liver oil—so frequently ordered—are most unsuitable and most provocative of so-called bilious attacks and cyclical vomiting. The most suitable diet is mainly carbohydrates, with the addition of glucose. I have been trying glucose now for some years on these children, and am highly satisfied with the results. A cocktail containing glucose, soda bicarbonate, and potassium bromide, taken before a party, has given most excellent results.

CONCLUSIONS.

1. Amyotonia in children is a condition accompanied by well-marked physical signs and symptoms.
2. Although the majority of these children are inherently nervous, some are not.
3. The condition is produced by exhaustion, mental and physical.
4. It is curable by mental and physical rest.
5. It is a common condition in all classes, and is becoming commoner.
6. The standing position of any child is the most important clue to its mental and physical health.

THE DUTCH PESSARY.

To the Editor of THE LANCET.

SIR,—In the annotation on Birth Control in your last issue you refer to the difference in size of the Dutch pessaries used at different clinics in this country. I began using this pessary just nine years ago, and introduced it to the profession at a congress held in 1922. (See THE LANCET, 1922, ii., 195.) I have used it in several thousand cases since then, and kept many of my patients under regular observation for periods varying up to as much as nine years. The pessary is made in 19 (not 14) different sizes, varying from 45 mm. to 90 mm. diameter, and I began nine years ago by using large sizes—seldom below 70 mm. But greater experience soon taught me that these sizes were too large for most women. They are so big that they must lie *very* obliquely in the vagina, and any increase of intra-abdominal pressure is likely to dislodge them so that they come to lie longitudinally in such a way that they no longer occlude the vaginal vault at all. For many years now I have used much smaller sizes, usually from 55 to 70, sometimes from 50 to 55, and rarely below 50 or above 70—and have got much more satisfactory results.

Mrs. Florence, in her careful study of 247 cases from the Cambridge clinic, classes 155 as failures. But of these 155 only 16, at most, are failures of the contraceptive to prevent conception; and Mrs. Florence herself says that she suspects 4 of these 16 of not having carried out full instructions. The other 139, for one reason or another, did not use the method, and therefore, obviously, cannot be counted as failures. The methods advised were certainly successful, *when used*, in 76 cases out of 92—i.e., in 82·6 per cent., so that Mrs. Florence's pessimism seems a little exaggerated. It is probable that the sizes recommended at the Cambridge clinic are, on the average, too large—rather than too small as you suggest.

I have frequently seen women who had been fitted by other qualified practitioners with pessaries so much too large as to be uncomfortable and unreliable. Indeed, in many cases the pessary could not be wholly inserted into the vagina at all, but protruded from the orifice. Perhaps the blame for this partly belongs to me, because formerly I advised as large a size as would lie in the vagina without causing discomfort. I therefore take this opportunity of warning against using a size so large that it will not fit properly into the vagina at all, or will only fit so obliquely that it may be dislodged by any ordinary increase of intra-abdominal pressure, or by the passage of fæces through the rectum. Bulging of the rectum, due to extreme constipation, may dislodge even the best fitting pessary. While this pessary is fairly reliable when used alone, its reliability is increased if the patient smears it before insertion with a jelly containing 1 per cent. lactic acid ("Contraceptalene"), and douches next morning before and after removal of the pessary. I have never seen a case in which this method has caused any ill-effects, nor have I been able to trace any such case in the literature.

The intra-uterine ring, to which you refer, has already been proved in one case to be fallible, though, in so far as it requires no care or intelligence on the part of the patient, it represents an advance in technique. I am, Sir, yours faithfully,

Harley-street, W., July 19th, 1930. NORMAN HAIRE.

A PROTEST FROM REGISTERED NURSES.

The Managing Director of the *Nursing Mirror and Midwives' Journal* has written in connexion with the letter under this title in our issue of July 19th, taking exception to an advertisement which appeared in the *Nursing Mirror* on June 14th. The Managing Director says: "This particular advertisement unfortunately slipped through by an oversight, and was published in one issue of the paper. On the morning of publication the management returned an order for further insertions of the same advertisement. On July 8th we received the letter of expostulation from the Royal British Nurses Association. A reply, a copy of which we enclose, was sent to them by return of post. It was not until July 12th that their letter of complaint was sent to you." The letter enclosed contains both an explanation and expressions of regret.

A PAMPHLET ON SPA TREATMENT.

THE Harrogate Medical Society have issued a pamphlet designed for the medical profession on spa treatment in general and on its application in Harrogate. The nature, aims, and methods of spa treatment are discussed and cases suitable for this treatment are indicated. Doctors desiring to send patients to Harrogate will welcome especially the sections on the routine adopted there, the length of visit advised, and the cost of "the cure." The authors of the pamphlet acknowledge that there is a certain amount of scepticism amongst their professional colleagues as to the efficacy of spa treatment, but point out that there are no more confirmed advocates of this particular health régime than medical men who have tried it themselves. The pamphlet and any further information required can be obtained from The General Manager, The Royal Baths, Harrogate.

IN THE MATTER OF AGE-LIMIT.

To the Editor of THE LANCET.

SIR,—It is good science, and should be good politics, to reconsider evidence periodically from as nearly unbiased a point of view as possible, in order that one may check one's beliefs or working hypotheses, whichever one chooses to call them, and perhaps discover new laws or modify old ones to suit the new data. Osler's suggestion of senility at 40 was made as a joke, but in view of much experience in applying for posts in various parts of the British Empire, I find that we are regarded as too old at 40 for most of the public posts, whatever may have been our past experiences, or our admitted suitability for a post. If you will consider the advertisements in your own pages, you will usually find that any post in either a Government or a Local Government service is only open to people under 35 years of age. A few of the higher type are open to those up to 40, but anything over is disqualified. This is said, when one asks why, to be due to the rule that such posts are pensionable, and that one must contribute to some scheme 5 per cent. of one's gross salary—as well as 4s. 6d. in the pound to income-tax—and

that it is expected that one will be able to give at least 20 years' service, otherwise 20 years for 19 years' pay. One is not allowed to waive pension rights, and cover one's own old age pension in one's own way, neither may one, however likely to serve for 20 years, get into the service if over this age-limit. We have succeeded in lengthening our life period considerably, and professional people are presumably of the higher type of mind, and so likely to be useful to the community for longer than the average man of I.Q.100 or so. Why, then, are the experienced to be barred just at the time when they are most likely to serve their community or country best? All honour to the young and enthusiastic, but at least some of us are middle-aged and enthusiastic, and have in addition experience which the young cannot yet have. Is it not now time that these rules for barring the older people were reconsidered and amended to give a chance to all who would serve their community in a public capacity, provided they are well qualified to do so?

I do not sign my name for obvious reasons.

I am, Sir, yours faithfully,

EX-TEMPORARY CIVIL SERVANT.

TYPOGRAPHY.

THE introduction of new founts of type into the pages of THE LANCET, and the general enlargement of the type employed, has led to several inquiries as to the history of the different forms of printing. Anyone who consults the article entitled Typography in the Encyclopædia Britannica will see how special the subject is; the famous founts of France, Italy, Germany, and Holland have in some cases known origins, and certain names, such as those of Plantin and Elzevir in the sixteenth century, are as familiar as the name of William Morris in the nineteenth century in connexion with particularly beautiful designs. In answer to one particular question—what is the type that has been employed in the main headings of the different sections in THE LANCET, we have this information; it is called "Caslon open," and William Caslon, who was among the earliest of the well-known English type-founders, flourished during the first half of the eighteenth century. As an illustration of the loving care with which the early types were made we may quote a note on the subject we have received from the Lanston Monotype Corporation. Speaking of the Italian types of Arrighi and Blado, the note says "these were most probably cut by a famous goldsmith from Perugia, Lautizio de Bartolomeo dei Rotelli, mentioned with commendation by Benvenuto Cellini himself."

THE MEDICINE OF AVICENNA.

To the Editor of THE LANCET.

SIR,—In a note with this title, published in your issue of June 28th, the photograph, as you rightly surmise, illustrates the entry to a tomb; it is that of Avicenna himself, at Hamadan, in Western Persia. I wrote an article in 1913 for the *St. Bartholomew's Hospital Journal* on A Pilgrimage to the Tomb of Avicenna. It led to a scheme for the conservation of the tomb, largely due to the late Sir William Osler. The war put an end to it, but money was collected in Hamadan by the local doctors, and the tomb and little garden were put in order. I saw it in 1920 and have a photograph.

I am, Sir, yours faithfully,

Highate, N., July 6th, 1930. A. R. NELIGAN, M.D.

QUEEN MARY'S HOSPITAL, SIDCUP.—This hospital, which has been purchased by the London County Council, was opened by Princess Mary Countess of Harewood on July 21st. The hospital was formerly the Queen's Hospital for Facial Injuries, and has been expanded to form a convalescent centre for 500 male patients from the Council's hospitals. Mr. Arthur Greenwood, Minister of Health, was present, and Dr. F. Barrie Lambert, chairman of the Central Public Health Committee of the Council, spoke of the reasons why the hospital had been acquired and the use to which it would be put by the Council.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, July 28th, to SATURDAY, August 2nd.—INFANTS HOSPITAL, Vincent-square, S.W., Special Course in Diseases of Infants. Every afternoon from 2.0 P.M. Lectures and Demonstrations. Further particulars from the Fellowship of Medicine.

Appointments

BRYCE, A. G., M.D., Ch.B. Manch., F.R.C.S. Eng., has been appointed Hon. Asst. Surgeon to the Salford Royal Hospital.

HUME, N. H., M.B., B.S.Dub., Certifying Surgeon under the Factory and Workshop Acts for Brecon.

RENNIE, J., M.D., Ch.B. Aberd., D.P.H., Prof. of Public Health in Sheffield University.

SAVIN, L. H., M.B., B.S., M.R.C.P. Lond., F.R.C.S. Eng., Consulting Ophthalmic Surgeon to the Whipps Cross Hospital.

Bolingbroke Hospital Incorporated, Wandsworth Common: GRAINGER, R., F.R.C.S. Eng. and Irel., Resident Medical Officer; HARDWICK, S. W., M.B., B.S. Lond., House Physician.

London Lock Hospital and Home: HERITAGE, K., F.R.C.S. Eng., Surgical Registrar to the Male Lock Hospital; WILLIAMS, LESLIE, F.R.C.S. Eng., Hon. Surgeon to the Male and Female Lock Hospitals.

Queen Charlotte's Maternity Hospital: HALL, EDITH M., M.D., B.S. Lond., Medical Officer, Antenatal Department; LLEWELYN-JONES, MARGARET, L.R.C.P. Lond., M.R.C.S., Resident Medical Officer, Isolation Block.

Births, Marriages, and Deaths

BIRTHS.

COLLEY.—On July 7th, the wife of R. Colley, M.B., Ch.B., D.O.M.S., The Circus, Bath, of a son.

MILL.—On July 16th, at Wilbraham-place, Sloane-street, S.W., the wife of W. A. Mill, F.R.C.S., of a daughter.

MITCHELL.—On July 11th, the wife of Dr. J. Myles Mitchell, Kingscote, Yeovil, Somerset, of a son.

THORNTON.—On July 13th, at Lisnanagh, Forest Fow, Sussex, to Muriel Thornton, M.B., wife of G. Kennedy Thornton, M.B.—a son.

MARRIAGES.

BURTON—SPARK.—On July 19th, at Bedford, Edward Burton, M.R.C.S., L.R.C.P., to Enid, elder daughter of Mr. and Mrs. Hubert Spark, Chaucer-road, Bedford.

BURTON—WOODROFF.—On July 19th, at St. Mary's, Wimbledon, David Henry Burton, B.Sc., to Dorothy Lilian Woodroff, B.Sc., M.R.C.S., L.R.C.P.

GROSS—FAGGE.—On July 17th, at St. Marylebone Church, William Stovell Gross, M.D., M.R.C.P., to Alice Bell Metcalfe, eldest daughter of Charles H. Fagge, M.S., F.R.C.S., and Mrs. Fagge, of Devonshire-place, W.

WILLIAMS—THWAITES.—On July 17th, at the Parish Church, Aspenden, Dr. A. Gregson Williams to Marjorie Patience, eldest daughter of Mr. and Mrs. J. K. Thwaites, of Aspenden Lodge, Buntingford.

DEATHS.

ASHWORTH.—On July 11th, at Worthing, James Henry Ashworth, M.D., late of Halstead, Essex, aged 82.

DYKES.—On July 15th, at Riselaw-crescent, Edinburgh, Thomas Dykes, L.D.S.F.P.S. Glasg., late of Dumfries, in his 75th year.

FRASER.—On July 17th, 1930, suddenly, at Pitlochry, Perthshire, Henry Fraser, M.D., M.R.C.P., aged 56, of Morney, Northumberland-road, Leamington Spa, formerly of Kuala Lumpur, Malay States.

GROGONO.—On July 19th, in a nursing home at Frinton-on-Sea, Dr. R. M. Grogono.

MACKENZIE.—On July 19th, at his residence, Fitzjames-avenue, West Kensington, Hector Graham Gordon Mackenzie, D.S.O., M.D., J.P., Lieutenant-Colonel, R.A.M.C. (T.A.), aged 62.

MIDELTON.—On July 16th, suddenly, Dr. W. J. Midelton, L.R.C.P., M.R.C.S., L.S.A., of Charminster road, Bournemouth, aged 67.

WILLIAMS.—On July 15th, at Spilman-street, Carmarthen, Dr. Edward Richard Williams, M.B.E., aged 70.

WOOD.—On July 19th, at Lodore, Chelston, Torquay, Thomas Outterson Wood, M.D., in his 88th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

ADDRESSES AND ORIGINAL ARTICLES

SYPHILIS OF THE HEART AND GREAT VESSELS.*

By Carey F. Coombs, M.D., F.R.C.P. Lond.,
PHYSICIAN, AND IN CHARGE OF THE UNIVERSITY CENTRE OF CARDIAC RESEARCH, GENERAL HOSPITAL, BRISTOL.

LECTURE I.

My immediate predecessor in this honourable office permitted himself a brief divagation into the history of the Lumleian lectureship, and brought back for our delectation a very interesting account of its founders. In this account he alluded to a fact which none of us can ever forget; that William Harvey filled this office for over 40 years, and that it was almost certainly in the exercise of its functions that he first proclaimed his views on the circulation of the blood. Whether this is so or not, his influence can be traced throughout the tenure of this lectureship. When its conditions were reconstituted, just over a hundred years ago, its first holder was Peter Mere Latham, who spoke "On Some Diseases of the Heart"; and its second John Elliottson who, though he is unhappily bettter remembered for his adventures in mesmerism, addressed the College "On the recent improvements in the Art of Distinguishing the Various Diseases of the Heart," an art in which he excelled, since he was one of the first British physicians to realise the value of the stethoscope. In more recent times the cardiological flavour imparted by the spirit of Harvey to this lectureship may again be discerned in the contributions of Osler, Norman Moore, Mitchell Bruce, De Havilland Hall, Sutherland, and Horder. To all of these, more or less, I am indebted, and of the first and last in particular I may say that to their lectures on "Angina Pectoris" and "Endocarditis" respectively I owe much of what I have to say in my own. To one other source connected with this College I have also to express my deep indebtedness, and that is to its treasurer, Dr. Sidney Phillips; for it is to his lectures at St. Mary's on cardiac disease, including as they did an unforgettable reference to the liability of the cardiosyphilitic to sudden death, that I owe my first interest in the matter.

But apart from personal reasons this subject has a compelling interest which, I think, justifies my choice. At first sight it may seem presumptuous to claim a territory which marches so closely with those surveyed by some of my immediate predecessors. In spite of this, however, it retains its individuality. It is true that it overlaps such areas as those of intrathoracic aneurysm, angina pectoris, endocarditis, and cardiovascular degeneration, all of which have within the past 20 years provided subjects for these lectures. Yet it is itself an entity, if this word can ever be applied to any group of natural phenomena; and since the progress of science has always been characterised by a derivation of causes from a study of effects, this way of looking at diseases as ætiological entities needs no apology. I propose, therefore, to lay before you an account of syphilis of the heart and great vessels, beginning with a brief survey of the development of our knowledge of the subject. This, together with a consideration of the part which syphilis plays as a cause of cardiovascular disease at the present day, will occupy my first lecture. In the second I propose to attempt a clinical portrayal of the disease, and in the third to expose the anatomical background of this picture, with particular reference to its mode of evolution.

Syphilis and Cardiovascular Disease.

In attempting to trace the growth of a belief in the importance of syphilis as a cause of cardiovascular disease, one is struck by the inexplicable delays which have marked several periods of its development. The association of aneurysm with syphilis was recognised almost as soon as syphilis itself became a common disease. To quote from Sir Humphry Rolleston's [45] Tercentenary Harveian Oration, which has laid all students of cardiology under an unlimited obligation:

> "The traumatic and superficial aneurysm was that mainly seen until syphilis became widespread after the return in 1493 of Columbus from the New World and the occupation of Naples by the army of Charles VIII. in 1495; there was then what has been called an unprecedented occurrence of aortic aneurysm. The association with syphilis did not escape Fernelius, who in 1542 first recognised internal aneurysms; Vesalius, who about 1557 diagnosed both thoracic and abdominal aneurysms; and Ambroise Paré (1582), who incriminated mercurial treatment as a cause of aneurysm. The luetic origin of aneurysm, though accepted by Lancisi (1728) and Morgagni (1761), waned; Matthew Baillie did not mention it in 1789 or later; but it was revived on good grounds in the middle of the last century by Crisp (1847), Myers (1871), Welch (1875) in this country, and by many foreign authors."

Now, during the earlier part of last century certain morbid anatomists described examples of another form of cardiac syphilis; a form so striking that it seems for the moment to have overshadowed the less dramatic aortic lesions that Hodgson [29] figured as preceding the formation of aneurysm. It was in 1845 that Ricord [44] described what appears to have been the first example of cardiac gumma, the exact nature of which was recognised; but not many others were added, and Virchow,[55] in a monumental article on the visceral lesions of syphilis published in 1858, brought forward from his own experience only one example of this lesion, occurring in a man of 47. In the preceding year Wilks[58] had described a case of fibroid heart which he attributed to syphilis, so that interest in the myocardial aspects of the disease had been awakened. Meanwhile, Hodgson and others had given some account of lesions of the aortic valves. As early as 1811 Corvisart[16] had attributed some of these to syphilis, but the lesions as he described them seem to have been polypoid growths of the kind seen in what we now call ulcerative or malignant endocarditis. Possibly they were examples of endocarditis of this type engrafted on a syphilitic basis. At all events the possibility of syphilis as a cause of valvular lesions is not even mentioned by Dominic Corrigan[15] in the paper in which, in 1832, he gave so clear an account of what he called "Permanent Patency of the Mouth of the Aorta, or Inadequacy of the Aortic Valves," although he stated clearly the fact that the aortic valves may leak by reason of dilatation of the aorta itself, and two of his figures are obviously those of syphilitic lesions.

This much, then, was recognised by the middle of the last century: the syphilitic origin of many aneurysms of the thoracic aorta; the fact that disease of the aortic wall precedes the development of aneurysm; the occasional determination of

* The Lumleian Lectures, 1930, delivered before the Royal College of Physicians of London.

gummatous and fibrotic processes to the cardiac wall, and the occurrence of insufficiency of the aortic valves.

Thereafter the study of this relation between syphilis and cardiac disease made but slow progress in spite of Clifford Allbutt's [2] and Heubner's [28] discovery of the syphilitic origin of certain peri-arterial lesions, and Welch's [57] emphatic reiteration of the importance of syphilis as a cause of aortic aneurysm in the British Army. Writing in 1876, he blamed syphilis for over 60 per cent. of these, and also described aortic nodulation as present in two-thirds of his post-mortem examinations of men who had had syphilis. In the latter part of the last century, Phillips's [42] paper showed that syphilis had to be reckoned with as a cause of cardiac disease in civil practice also. General recognition of the truth and significance of these doctrines was, however, delayed until the present century, when fresh light shone into this dark corner from two different angles. On the one part the infective nature of syphilis, always suspected on general grounds, was clearly demonstrated by Schaudinn and Hoffmann. This was followed by the discovery of the complement-fixation test and its applicability to the diagnosis of syphilis. These two steps forward were inevitably succeeded by a third, when Ehrlich brought forward his synthetic arsenical preparations for the extinction of the spirochæte. Thus we advanced to a point from which the whole field of activity of the syphilitic virus might be resurveyed, and thus it was that the aortic lesions—their frequency, their nature, and their gravity—came to be revalued. At the same time the study of cardiac disease in its physiological aspects, in its relation to disturbance of function, was awakening new interest in the intracardiac localisation of morbid processes. We cannot too often remind ourselves of the honourable part played by Fellows of this College—Allbutt, Mackenzie, Lewis, Wenckebach, and others—in this advancement of our learning. One immediate and practical outcome was a renewed interest in the distribution of the lesions of syphilis within the heart.

It is not a matter for surprise, therefore, that the past decade should have produced a large number of papers on cardiovascular syphilis. When I first determined upon the choice of that subject I hoped that I should be able to lay before you a critical summary of all this work, but when I tried to do so I was confronted by three principal difficulties. In the first place, many of the points on which I felt doubtful or uncertain did not seem to be noticed at all in this new literature. Secondly, other points proved controversial, one author expressing views diametrically opposed to that of another. Finally, the bulk of the papers was so great and some of them were so inaccessible that I felt obliged to fall back on my own observations in order to secure the necessary data. By way of furnishing a basis for this review of the subject, I have analysed the records of 103 patients with cardiovascular syphilis whom I have seen, both in private and in hospital practice, since the war. That these are all of them authentic cases of syphilitic infection would, I think, be agreed by everyone. In each there was either a history of syphilitic infection or clinical evidence of some other syphilitic lesion, or a positive reaction to the Wassermann test, or the post-mortem appearances characteristic of syphilitic disease of the heart and aorta. These records have not been in any way selected. The only process of selection was in fact a process of rejection; records of 21 other cases were omitted on the ground that the syphilitic nature of their troubles was not incontrovertibly established. I should not, however, venture to base a comprehensive account of any group of lesions on clinical data alone. Accordingly, I enlisted the help of my colleague, Dr. A. L. Taylor, pathologist to the Bristol General Hospital, and I shall refer to figures extracted from our post-mortem records which he has kindly set out for my use; and to a similar series of data for which I am indebted to Dr. E. R. Cullinan, of St. Bartholomew's Hospital. I have also made a microscopical examination of the heart and aorta in 21 cases of cardiovascular syphilis. These experiences have helped me once more to realise how much there is to be said for the plan of conjoining clinical with anatomical examination. It would, I think, be difficult to get as clear a mental picture of this or, indeed, of any other disease by either method of observation alone. On the one hand the resort to histological inquiry has made the clinical phenomena much more intelligible, while on the other hand the clinical observations give a sense of life to the picture which it would lack if it were drawn from anatomical data alone.

THE FREQUENCY OF CARDIOVASCULAR SYPHILIS.

The data which Dr. Taylor extracted from our post-mortem records are arranged to show, first, in what percentage of all autopsies we may expect gross cardiovascular disease; and secondly, what percentage of that disease is syphilitic. In 1750 post-mortem examinations 354, or 20 per cent., showed cardiovascular lesions; and of these 45, or 12·7 per cent.—almost exactly one-eighth—were syphilitic in type. Dr. Cullinan's figures from St. Bartholomew's Hospital were drawn from 1000 consecutive autopsies on cases from the medical wards. Of these, 456 showed gross cardiovascular disease, which was syphilitic in 33 cases, or in 7·2 per cent.

These data may be compared with some other series:—

TABLE I.

Author and city.	Date.	Number of autopsies.	Cardio-vascular syphilis in: %
Symmers [51] (New York)	1916	4,880	175 (3·5)
Reid [43] (Boston)	1920	1,678	54 (3·2)
Cowan [16] and Faulds (Glasgow)	1929	1,000	60 (6·0)
Taylor (Bristol)	1919–29	1,750	45 (2·5)
Cullinan (London)	1920–26	1,000	33 (3·3)
Clawson [9] and Bell (Minneapolis)	1910–26	4,577 (Pts. over 20)	126 (2·6)

The proportion of cases of fatal syphilis in which aortic lesions are found differs a good deal according to different observers. I have examined many of these statistics, and propose to accept the estimate offered by two experienced observers working on large aggregates of material: Turnbull, [52] of the London Hospital, who found aortitis in 60 per cent. and aortic valvular disease in 15 per cent., and Symmers, [51] of New York, who noted aortic lesions in 55 per cent.

During the twelve years 1918–29, inclusive, I saw and kept notes of 2089 cases of organic cardio-vascular disease. Of these, 100, or nearly 5 per cent., were certainly syphilitic in origin. If to these be added another 21 of doubtfully syphilitic origin, the percentage is raised to nearly 6. If I had limited my inquiry to hospital patients the share of cardiac lesions due to syphilis would have been 8·4 per cent.

Heimann's [27] series, which he was good enough to prepare for me, raises one interesting question; in it the proportion of cardiovascular disease due to

syphilis was as high in Europeans as in negroes. This contradicts the impression received from talks with medical men who have practised in countries with a large negro population, yet it is supported by other evidence. Donnison,[19] of Kenya, has expressed the view that cardiac syphilis is rare among negroes, and this has been the experience of friends of mine at work in different parts of Africa—Drs. C. C. Chesterman, Alan Bodman, A. J. Keevil, and H. W. Brassington—who kindly supplied me with this information. On the other hand, we have American evidence in support of

TABLE II.—*Clinical. Percentage of all Cardiovascular Disease due to Syphilis.*

Author and city.	Total cases.	Percentage due to syphilis.
Coombs (Bristol)	2,047	5·0
Wyckoff and Lingg (New York)	1,001	9·0
Coffen (Portland, Oregon)	1,673	4·1*
Harris (Liverpool)	—	9·0
Heimann (Johannesburg)	253	15·0

* 5·0 per cent. if organic disease only is included.

the view that negroes are more liable than whites to this disease. Wyckoff [61] and Lingg found that in New York the proportion of cardiovascular disease attributable to syphilis was more than twice as high in negroes as in white patients; and the experience of Swift [50] and Kimbrough, in a Southern State, was to the same effect. Apparently the negro is only more liable to exhibit signs of cardiac syphilis in so far as he is liable, when exposed, to be infected by syphilis. That the syphilis attack-rate in these States is much higher among negroes than among whites may be deduced from a recent paper by Cutting,[18] Loria and Pickell, of New Orleans, and from others from similar sources.

Another contrast is that between the frequency of cardio-aortic syphilis as estimated clinically and its incidence at post-mortem examinations. In our Bristol General Hospital series, for example, the post-mortem incidence was half as large again as that of the cardiosyphilitics as defined clinically. To this discrepancy several influences contribute. One is the liability of these patients to sudden death. Such victims as these find their way into the pathological statistics, but for the most part fail to be observed and recorded by the clinician. Again, there is no doubt that a certain proportion of cardio-aortic syphilis is subclinical in degree. There are lesions that can be seen with the naked eye in an early stage, yet they have not reached the point at which symptoms are produced. In this, cardiac syphilis resembles neurosyphilis. By the time that symptoms appear, whether cardiac or nervous, the anatomical changes on which these depend are already advanced; for Nature has endowed vital tissues with so wide a margin for emergencies that destructive agencies can only evoke those expressions of organic inadequacy that we call "symptoms" by inflicting gross injury, gross enough to destroy a large share of that margin.

There are two other reasons that may help to account for some of this discrepancy between clinical and pathological percentages. The first of these is the somewhat conservative view, that I must confess I hold, as to what constitutes satisfactory ground for a diagnosis of cardiac syphilis. No one would, I think, argue that any of the cases to be discussed presently should be excluded from this paper; but some might say that others ought to have been included. As examples, I have in my mind three patients. One, a man of 46, presented signs of mitral stenosis with auricular failure and also symptoms of locomotor ataxia. The second, a woman, also in middle life, showed exactly similar cardiac signs, with a liability to miscarriage and a positive Wassermann reaction. The third, a girl of 9, a congenital syphilitic whose tabetic father was also my out-patient, displayed signs of early mitral stenosis, together with a typical rheumatic chorea. I have excluded all of these from my group of cardio-syphilitics, on the ground that the lesion displayed—that of mitral stenosis—was one which could not conceivably owe its origin to syphilis, any more than the tabes of the first of these three could be attributed to the rheumatic infection that had injured his heart.

One other reason for the discrepancy under discussion is that pathologists find it almost as difficult as do clinicians to discriminate between what is and what is not syphilis. For this we have to thank the influence of atheromatous change, so often to be seen in those very persons who also exhibit the aortic lesions of syphilis. Not only do these two processes often impinge simultaneously and almost inseparably from one another on the aorta itself, but also, even when the syphilitic lesion has the aorta to itself, its ravages are found to be supplemented by atheromatous disease in the coronary trunks. As a result of this confusion I feel sure that there is a tendency at the present time to label as syphilitic, on the score of the naked-eye appearances, cardiovascular lesions which histological examination would discover to be degenerative.

When we consider all these factors, then, it is not surprising that we find an appreciable discrepancy between clinical and pathological views as to the part played by syphilis in accounting for cardiovascular disease. The frequency of cardiovascular syphilis may be summarised by saying that when we are confronted by an organic lesion of the heart there is a chance of its being syphilitic that varies from 5 to 15 per cent. in different parts of the world.

RESPONSIBILITY OF SYPHILIS FOR CERTAIN KINDS OF CARDIAC DISEASE.

About the part of syphilis in the causation of thoracic aneurysm there is no room for doubt. Camille Lian found evidence of a syphilitic origin in 83 per cent. of his cases, and this accords closely with the experience of most observers from Francis Welch [57] onwards. Abdominal aneurysms are far less often syphilitic. This accords with Turnbull's [52] observation that aortic syphilis is found most often in the first part of the thoracic arch, more than four times as often as in the abdominal portion. It is that stretch of aorta from the sinuses of Valsalva to the origins of the main trunks supplying the head and arms that suffers most, and it is from this stretch that nearly all syphilitic aneurysms arise. For the following data, from the Leeds General Infirmary, I am indebted to Prof. M. J. Stewart and Dr. H. G. Garland.

TABLE III.—*Frequency of Syphilitic Aneurysms in Different Situations.*

Site.	Total number of aneurysms.	Syphilitic.	Percentage of total.
Aorta—			
Ascending	37	32	88·8
Transverse	21	15	71·4
Descending	19	11	57·8
Abdominal	14	5	35·7
Heart	27	3	11·6

In fact, we are justified in assuming that a saccular aneurysm arising from the aortic arch is syphilitic unless there is strong evidence in favour of an alternative view.

About aortic incompetence, however, there is wide difference of opinion. My own Bristol figures show that of 130 hospital in-patients with signs of aortic incompetence 39, or 30 per cent., were syphilitic. Cowan [16] and Faulds found in Glasgow that of 224 patients with aortic incompetence 32·1 per cent. owed their lesion to syphilis. Harmer,[25] scrutinising a series of 467 cases of aortic incompetence, held syphilis responsible for 37·3 per cent. of all those patients whose ages lay between 20 and 70, and

pointed out that 35 was the watershed age between rheumatism on the one hand and syphilis on the other. On the other hand, Longcope,[38] in 1913, thought that three-quarters of the cases of aortic regurgitation seen in adult life were syphilitic. More recent series by Wittgenstein [59] and Allan [1] arrive at a closely similar result. Here it is likely that a good deal of the divergence may arise from a different conception of what is meant by aortic incompetence. Some of the higher estimates are probably based on series from which cases exhibiting additional cardiac lesions, such as mitral stenosis, have been excluded. In our own figures we are speaking of all cases in which a leak in the aortic valve has been detected, no matter what other lesions may have been present. Camille Lian, discriminating between the rheumatic and the non-rheumatic kinds of aortic leak, found a positive Wassermann test in one out of nine cases of the former and 88 out of 108 cases of the latter. It is obvious that the percentage must vary widely, not only with the incidence of syphilis, but also with that of rheumatism, an infection showing such wide geographical variations as to render comparisons between one series of figures and another almost worthless.

Although in my view the use of the term "angina pectoris" is to be deprecated, since it tends to exalt to the status of a syndrome that which is no more than a symptom, yet it is convenient to glance for a moment at those conditions in which præcordial pain excited by effort is the outstanding experience. In a group of 249 patients whose troubles were of this kind, 38, or 15 per cent., came from the syphilitic category. In other words, the share borne by syphilis of the responsibility for kinds of organic disease in which præcordial pain on effort occurs is three times as great as it is for organic heart disease in general, where its share is only 5 per cent. By way of comparison, I have worked out the share borne by the other forms of cardio-arterial degeneration—the hyperpietic and the senile—of these same 249 examples of ischæmia cordis; and I find that these two degenerative influences accounted for 62 per cent., whereas these same categories were only responsible for 42 per cent. of the whole mass of organic heart disease. The comparison, therefore, works out as follows: whereas the hyperpietic and the decrescent classes of cardio-vascular degeneration account for one and a half times as big a share of the pain syndromes as of cardiac disease in general, the corresponding ratio in the case of syphilis is as 3 to 1. In other words, syphilis, when it attacks the cardiovascular apparatus, is twice as likely to involve its victim in a liability to præcordial pain on effort as are the more common forms of cardio-arterial degeneration. This relation, between syphilitic infection of the aorta and heart and cardiac pain, also possesses a particular interest for me, since it was an anomalous feature of this relationship that caused me to re-examine the whole subject. When analysing the conditions under which cardiac infarction occurs, I was greatly surprised to find how small a part syphilis takes in preparing the stage for this tragedy. On inquiry I learnt that this had been the experience of other observers also. For instance, in Levine's [35] large series of cases of coronary thrombosis the Wassermann test reacted positively in only three of the 89 cases to which it was applied; and of the 46 cases examined post mortem, only two showed aortic syphilis. In my own practice, of over 100 cases where I have made a diagnosis of cardiac infarction, generally on the ground that severe sternal or epigastric pain has been followed by evidence of gross damage to the cardiac wall, the background has been syphilitic in one only. This formed so striking a contrast with the incidence of cardiac pain without subsequent organic change that I was moved to institute a careful comparison between the ætiology of these two syndromes. The results of that comparison were to show that, whereas syphilis is a leading cause of cardiac pain without organic sequelæ, it takes but a small part in bringing about coronary occlusion. The reason for this anomaly will appear when the anatomical state of the syphilitic heart comes to be discussed.

Cardiac pain is so often an early symptom o what in my own nomenclature is, perhaps presumptuously, entitled "ventricular failure," that I pas naturally to a consideration of other aspects of thi kind of cardiac defeat. Parkinson [41] and Bedford, i discussing the causation of that which they describ as "heart failure with normal rhythm," found syphilitic element in 21 out of 100 cases. Thi is that same form of heart failure that Herapath [11] an I ventured to label "ventricular," and my own dat agree with those quoted in ascribing a prominen share in its production to syphilis. In another pape Herapath [12] and I analysed a group of 163 cases o what we called "auricular failure"—the type o breakdown that is often designated "fibrillation or "total arrhythmia," both of them unsatisfactor labels since each denotes only one aspect of the whol affair—and found only three, less than 2 per cent., i which syphilis was known to be a cause.

Finally, there is the question of heart-block When this category of cardiac failure was first define the gummata seemed likely causes, and indeed som examples were described; for instance, a remarkabl case reported in 1906 by Keith [32] and Charles Mille Possibly the wish was father to the thought; w hoped that we were being led to a new chapter i cardiovascular therapeutics, wherein localisation function would pave the way for triumphant attack upon circumscribed areas of disease. Be that as may, it is now clear that syphilis is not a commo cause of heart-block. My colleague Dr. Herapat stated that in his series of 20 cases of heart-bloc only two had been syphilitic. The experience Gallavardin [22] has been identical; of 39 cases of heart block three were undoubtedly and one possibl due to syphilis.

These glimpses of the chief cardiac syndrome have shown us, then, that syphilis plays the leadin part in the production of aortic aneurysm and a important part in rendering the aortic valve inadequate; that it takes almost as large a shar of responsibility for failures of the ventricular typ and for stenocardia of the transient degree, but not of much account in causing cardiac infarctio auricular failure, or heart-block.

Age- and Sex-incidence.

The impressions on which this clinical pictur is based are derived from a study of the 100 patient of whom I have already spoken, with three othe seen during the current year. The incidence of th disease in regard to age and sex was not differen from that in the series published by other observer The average age at which symptoms were firs experienced, in 52 cases in which this was ascertaine was 49·6 years, the extremes being 32 and 64 year Mitchell Bruce,[6] in his Lumleian lectures, found tha the syphilitics in his series of cardiovascular degenera tions felt their first symptoms at an average ag of 49. The age-incidence of Dr. Cullinan's autops cases was as follows:—

Only one under 37 years (aged 28).			
37 to 40	years	.. ..	5 cases.
40 to 45	,,	.. ..	2 ,,
45 to 50	,,	.. ..	7 ,,
50 to 55	,,	.. ..	6 ,,
55 to 60	,,	.. ..	7 ,,
Over 60	,,	.. ..	4 ,,

The time that had elapsed between infectio and the onset of symptoms averaged 22·7 yea in my patients. This is a little longer than i most series, but in Mitchell Bruce's cases it wa longer still—25 years. This long incubation perio that elapses between the invasion of the body b the virus and the development of symptoms cardiovascular disease brings these lesions into th

ame epoch of the infection as locomotor ataxia and eneral paralysis. It is surely no accident that here is so close a likeness between these two ets of syphilitic phenomena, the cardiac and the ervous. The disease has evolved in the same way, nd the only differences that are to be noted are due o the differences of function. We are to expect a ather earlier outcry on the part of the nervous ystem, since it is always a more sensitive index of isease than any other part of the body; and this is vhat happens in syphilis. The earliest symptoms f tabes and general paralysis are noted, on an verage, at an age that is a little earlier than the ymptoms of onset of cardio-aortic syphilis.

There is a similar correspondence between the wo sets of lesions, the cardiovascular and the ervous, in respect of their sex-incidence. Actually 0 per cent. of my patients were males, and this reponderance is found in most series, though in ur post-mortem series the females accounted for 9 per cent., an exception that I do not here ttempt to explain. I can see no strong reason for upposing that the sex-incidence of these later yphilitic phenomena is in any way deceptive. It s usually taught that women are less likely to seek arly treatment for syphilis than men are because he primary lesion is so much easier to overlook in omen than in men. This being so, the scales etermining the probability of effective treatment re heavily weighted in favour of the man. If, in pite of this, men are more apt to develop late syphilis f vital organs, is it not probable that this liability presents a corresponding liability on the part of en to contract syphilis? This is what I should ave expected, for it is to be presumed that most en contract syphilis from intercourse with a rostitute, and it is also to be presumed that an fected prostitute passes on the infection to more an one man. Dr. Hardy Kingston, who is in harge of the Venereal Disease Clinic in Bristol, lls me that during 1929 the new cases of syphilis mong men were four or five times as numerous s among women, and I imagine this is an average xperience. In congenital syphilis of the aorta there s, as far as I can discover from the records, no strong redilection for the males; and this impartiality ay not unreasonably be ascribed to the fact that hen infection is conveyed through the medium of he placenta to the unborn child there is no way in hich the sex of the victim can affect the matter.

Two other points are worthy of note in connexion ith the aortic lesions of congenital syphilis. One that the incubation of these lesions is if anything horter than it is in the case of acquired syphilis. n many of the recorded instances the diagnosis was ade before the patient had reached the age of . Congenital syphilis is fortunately becoming less common disease, and it is therefore to be hoped at the future will hold little opportunity for investiation of the reason for this; but it is perhaps not nciful to see in the shorter incubation an expression the intense nature of the infection in inherited as mpared with acquired syphilis. Here, again, as the sex- and race-incidence, we seem to discern a rect proportion between the total force of the fection and its aortic consequences. The more able the subject is to syphilis, the more liable he is syphilitic aortitis; and this relation is so nearly rect that there seems little need to introduce other edisposing factors to explain away the greater bility of the male.

In congenital syphilis of the heart and aorta, in the acquired disease, the aortic lesions fall into the same epoch as those of the cerebro-spinal axis—i.e., they appear at roughly the same interval after birth. Once again, then, we are reminded of the close similarity between the age- and sex-incidence of cardio-aortic syphilis on the one hand and that of cerebro-spinal parasyphilis on the other.

A PROTEOSE IN THE URINE,

EXCRETED IN ANAPHYLACTIC AND ALLERGIC CONDITIONS.

BY G. H. ORIEL, M.D. CAMB.,*
ANDERSON DEMONSTRATOR OF CLINICAL CHEMISTRY, GUY'S HOSPITAL;
AND
H. W. BARBER, M.B. CAMB., F.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF SKIN DEPARTMENT, GUY'S HOSPITAL.

IN a previous communication[1] we reported that, if the urine from cases of allergic and febrile diseases is acidified with sulphuric acid and shaken with a fifth of its volume of ether, the ethereal layer formed on standing, instead of being for the most part clear, as in normal people, becomes opaque, and has a waxy appearance. In strongly positive cases we noted that the tube could be inverted without spilling the contents. We have since found that,[2] if this reaction is carried out in a separating funnel and the lower layer run off, the supernatant layer, when shaken with an equal volume of alcohol, yields a precipitate of a complex nitrogenous substance, which has interesting biological properties.

A 24 hour specimen of urine is collected from a case showing active symptoms, and put in a Winchester bottle containing a little chloroform. Approximately 400 c.cm. is placed in a separating funnel, rendered acid to Congo red with sulphuric acid, and shaken with 100 c.cm. or less of ether. Should the specimen contain urates, it is rendered alkaline with dilute caustic soda to dissolve them, and subsequently made acid. When the two layers are separated, the ethereal layer is treated with an equal volume of alcohol, and the precipitate allowed to settle. The latter is then collected by centrifuging in a sterile centrifuge tube. This tube is inverted in an incubator at 37° C., and the alcohol and ether, present in the precipitate, are allowed to evaporate. When dry, the precipitate is dissolved in sterile N/10 sodium hydrate. The quantity of sodium hydrate required varies with the case, but 2 or 3 c.cm. are usually sufficient. Taking the usual aseptic precautions, 1 c.cm. of this solution is added to 9 c.cm. of 0·5 per cent. phenol dissolved in normal saline. We are accustomed to call this dilution 1 in 100 for convenience. The quantity of precipitate obtained is usually about 0·3 g., so that the NaoH solution is approximately 1 in 10, but, as weighing each precipitate would involve loss of sterility, the exact quantities are ignored. Further dilutions of 1/1000, 1/10,000, 1/100,000, and 1/1,000,000 are made. The sterility of the solution is then tested by inoculating an agar slope, and incubating for 48 hours. If care is taken, the solutions are usually sterile. The chloroform in the 24 hour specimen, and the subsequent treatment with ether and alcohol, seem to kill the contaminating organisms. This is fortunate, as heating destroys some of the properties presently to be described.

Chemical Properties.

The chemical properties of this precipitate are complex, and it appears to belong to the ill-defined group of the proteoses. An exact analysis has not yet been carried out, but an aqueous solution gives the following reactions. The Biuret test is positive, a violet colour being obtained. Millon's reaction is also positive, as is the xanthoproteic. The presence of

* Working with the aid of a grant from the Medical Research Council at the Asthma and Dermatological Clinics, Guy's Hospital.

carbohydrate is indicated by the positive reaction to Mollisch's test. On hydrolysis and analysis by Kossel's method,[3] histidine, arginine, and lysine are found to be present, also various mono-amino acids. It is not coagulated by heat, but is precipitated by heavy metallic salts such as lead acetate, and by alcohol. It is not completely precipitated by half saturation with ammonium sulphate, but is by full saturation. When the substance is hydrolysed with dilute hydrochloric acid a brown precipitate is obtained; this contains phosphorus, and is presumably nucleic acid. From the filtered products of hydrolysis we have succeeded in making an ozazone. It must be remembered that normally a small quantity of mucus is present in urine, secreted by the epithelium of the urinary tract, and this would be extracted by the method outlined above.

We have recently attempted to obtain quantitative figures of the amount of this "proteose" present. This has been done by extracting it from 100 c.cm. of urine, and estimating the contained nitrogen by the method of Kjeldahl. It is found that in the "normal" person (students and laboratory workers in apparent health) the daily output of nitrogen, recovered by this method, varies between about 7 mg. and 25 mg. per diem. Table I. shows comparative figures in health, and in some conditions which we have had the opportunity of investigating.

This method will probably be found to provide a simple means of estimating quantitatively the "albumose" which has long been known to exist in febrile urines (Wells). We are here concerned with this substance in its relationship to allergic conditions. We will refer to it as "proteose," although it is obvious from the analysis given above that it may contain nucleoprotein, and even glucosamines.

In a case of anaphylactic shock following the intravenous administration of a very small quantity of antidysenteric serum, previously described,[1] the chief urinary findings were as follows:—

1. For the first six and a half hours after the onset of shock there was complete anuria. After this, very small quantities of highly acid, concentrated urine were passed. The followed the post-paroxysmal diuresis.

2. The first specimen of urine passed deposited urates and the first three contained albumin.

3. The free acidity rose very markedly during the firs 12 hours; during the post-paroxysmal diuresis it fell to low figure. The ammonia excretion, relatively high a first, remained so during the diuresis, thus disturbing sti further the ratio of free-acid to ammonia-combined acid.

4. The ether reaction was very strongly positive in th first specimen obtained, and remained so until the diuresi was established; it was still positive on the morning of th third day.

In this case the diuresis did not occur until th evening of the day after the shock.

Recently we have had the opportunity of observing a case of serum sickness, following the administration o antidiphtheritic serum.

A CASE OF SERUM SICKNESS.

The patient, a medical man aged 25, had had three previou injections of antitetanic serum, the last about one and a hal years ago. He was given a prophylactic dose of anti diphtheritic serum, having been coughed at by a child wit diphtheria. Four or five days later (the short incubatio period being doubtless due to the previous injections c serum), the symptoms of serum sickness began. He wa seen by us at 11 A.M. on Dec. 31st, 1929, after a very uncom fortable night, and having had complete anuria; at tha time there was generalised adenitis, his expression was pal and anxious, and a profuse urticarial eruption was appearing He was instructed to collect all the urine passed, and wa seen again at 2.30 P.M., at which time the urticaria wa intense. An injection of adrenalin was given, whic temporarily relieved the itching, and he was put to bed an ordered large quantities of powdered glucose in lemonade Until 1.30 A.M. on Jan. 1st, 1930, only 315 c.cm. of urin were passed; at this time diuresis began, and between 1.3 and 4 A.M. he passed 2010 c.cm. This diuresis was accom panied by a great amelioration of the symptoms, and b 8.30 A.M. the urticaria had disappeared and he felt com paratively well. There was no relapse.

Tables II. and III. summarise the most importan urinary findings in these two cases:—

M. = Midnight. A-c. A. = Ammonia-combined acid.

It should be noted in the second case (Table III. that:—

1. The three specimens obtained before diuresi began deposited urates, and gave very strong ethe reactions.

2. The ammonia excretion was very high, thu causing a marked alteration in the free-acid :: ammonia combined-acid ratio.

3. With the onset of diuresis there was a sudden drop in the free-acid and to a less extent of the

ammonia combined-acid, and urates were no longer deposited.

4. The ether reaction became negative, and no proteose could be obtained.

It will be seen that the cycle of events in these cases —one of serum anaphylactic shock and one of serum sickness—is practically the same, and is comparable to that previously described as characteristic of allergic conditions, such as the prurigo of Besnier with asthma, infantile eczema, urticaria, and angeioneurotic œdema.[1] It should be noted, however, that in the first case the onset of symptoms, which were those of profound shock, occurred while the serum was actually being injected, whereas in the second there

was an incubation period shorter than usual — presumably because antitetanic serum had previously been given on more than one occasion. This latter case threatened to be a severe one of serum sickness, and the symptoms would have been expected to continue for some days. We consider it probable that the rapid recovery can be attributed to the administration of large quantities of glucose; it is possible that, if given just before and for several days after injection of foreign serum, powdered glucose might prevent serum sickness, or, if taken in large doses at the onset, might—as apparently in our case—abort the attack. Further observations on long series of cases are, however, obviously required to establish this suggestion.

Proteose Tests from Urine in Serum Sickness.

The proteose, isolated from the urine of the case of serum sickness referred to above, was put up in various dilutions for certain tests to be detailed below:—

At midday on Jan. 2nd, 1930, 0·1 c.cm. of the patient's own serum, obtained during the period of active symptoms, was injected intradermally in the left forearm of one of us (H. W. B.) at two sites (*a* and *b*). At 4.45 P.M. on the following day, 0·025 c.cm. of a 1/100,000 dilution of the proteose was injected intradermally into one of the sites (*a*) and into the other site (*c*) not previously injected with serum; into site (*b*) 0·025 c.cm. of the same dilution of the proteose obtained from the urine of another patient (a case of prurigo) was injected. At 6.30 P.M.—i.e., one hour and three-quarters later—there had developed at site (*a*) an oval wheal about half an inch in size, surrounded by a zone of bright erythema ("flare"). At sites (*b*) and (*c*) small circular wheals without flare were apparent, corresponding in size merely to the elevations produced by the intradermal injections of proteose solution. At 9.30 P.M. the wheal at (*a*) was of about the same size, but had developed a finger-like prolongation from its lower border; the "flare" had almost disappeared. The small wheals at (*b*) and (*c*) had diminished in size, the latter being hardly visible. At 11.45 P.M. the wheal at (*a*) was slightly smaller, but the prolongation had increased in length. There were but traces left of those at (*b*) and (*c*). At 10 A.M. the following morning there were still the flattened remains of the wheal at (*a*) with its prolongation. Nothing but the puncture marks could be seen at (*b*) and (*c*).

The experiment corresponds to the Prausnitz-Küstner reaction. Two areas of skin of a normal person were injected with the serum of a patient in a state of allergy towards horse-serum; as is well known, the antibodies contained in the sensitised serum are fixed by the skin at the site of injection, so that when, 24 hours later, the specific antigen is injected at the same site, an urticarial wheal results. Of the two areas thus sensitised the one (*a*) developed a characteristic wheal of considerable size, with a temporary flare and lasting many hours, after injection of the patient's proteose in high dilution, whereas the other (*b*) gave no response to the proteose of another patient; the non-sensitised area (*c*) did not react to the proteose of the case of serum sickness, which was also injected into another normal subject without response.

Intradermal injections in a dilution of 1/100,000 of the proteose obtained from this case of serum sickness were then made in three subjects known to be horse-sensitive, and positive reactions were obtained. Proteose in the same dilution from an allergic patient, non-sensitive to horse, gave negative reactions. In one of these patients—a horse-asthmatic—the intradermal injection of the proteose from the patient with serum sickness was followed by rhinorrhœa and slight asthma the same evening, although he had not had these symptoms for some time previously.

From these experiments one may conclude that the proteose contained the antigen to which the patient was sensitised, and their importance lies in the fact that the nature of the primary antigen was known.

Two similar experiments were also made by one of us (G. H. O.) in cases in which the antigen was unknown. In a case of migraine the patient's blood was obtained during an attack, and the serum was injected intradermally at two sites in G. H. O.'s arm. The proteose prepared from the urine, collected during the attack, was put up in a dilution of 1/10,000, and on the following day tested on one of the sensitised areas of skin by the scratch method; a wheal with surrounding "flare" resulted, whereas the proteose from a case of asthma in the same dilution gave a negative response when scratched into the other sensitised area. An intradermal test with the proteose from the case of migraine on an unsensitised area of skin was negative. The experiment was repeated in a case of dermatitis herpetiformis with the same result.

It would thus appear justifiable to believe that the proteose excreted in the urine in allergic states contains the active antigen, probably, as will be seen, in combination with the products of tissue autolysis. This view is confirmed by the extraordinary sensitiveness of certain patients even to intradermal injections of minute quantities of their own proteose, and by the therapeutic effect of repeated injections. In the description of the chemical properties of the proteose it was remarked that, when it is hydrolysed with dilute hydrochloric acid, a brown precipitate is obtained, which contains phosphorus and is presumably nucleic acid. Lewis,[4] in an account of his studies with Grant of a person highly sensitive to fish, remarks in a footnote that the active substance in the fish extract employed "appears not to be a coagulable protein, nor is it histamine; Dr. C. R. Harington regards it as associated with nucleic acid. . . ." It is possible, therefore, that the antigenic moiety of urinary

proteose is the part that yields a phosphorus-containing substance on hydrolysis with hydrochloric acid.

Significance of Urinary Proteose.

It must be clearly understood that, as will be seen from Table I., a small quantity of proteose can be recovered from the urine of a normal person in apparent health, but that, when this is scratched or injected into his skin, no local or general reaction results. The total quantity of proteose excreted in the urine is relatively large in acute infections, in anaphylaxis, and in acute and chronic allergic conditions, but from the practical standpoint it is the antigenic moiety that is of importance. In allergic conditions with recurrent crises—e.g., urticaria and certain cases of asthma and prurigo—it is essential that the urine be collected throughout a period that covers the paroxysm, in order that the antigenic substance may be obtained. In chronic conditions, such as psoriasis and rheumatoid arthritis, in which there are no recurrent paroxysms, a 24 hours' specimen of urine should be collected. We have found, for example, in urticaria and asthma that the proteose, isolated during a quiescent period, may give negative cuti- and intradermo-reactions, whereas with that obtained during the stage of active symptoms the reactions are positive.

It is well known that some of the symptoms of anaphylactic and allergic reactions in general, such as urticaria and the contraction of plain muscle in certain organs, may be explained in the light of Lewis's [4] researches as resulting from the local liberation of histamine from sensitised cells, owing to the contact of antigen with the antibodies contained in them. Further, as Dale [5] suggests, anaphylactic injury of the cells of an organ like the liver might liberate histamine into the general circulation in sufficient quantity to cause a reaction in cells of other tissues, not themselves sensitised to the antigen, but sensitive to histamine. Manwaring [6] and others have shown that in dogs sensitisation to an antigen is confined almost entirely to the liver-cells; as a result of anaphylactic damage to them, a substance having histamine-like effects (anaphylotoxin) is liberated, and produces its characteristic action not only on the vessels of the liver itself but also on plain muscle structures elsewhere in the body. Dean,[7] from his post-mortem examination of a case of fatal anaphylactic shock, has pointed out the similarity between such shock in man and in the dog, the chief and essential change in both being in the liver, and we would here emphasise again the evidence of hepatic damage, as revealed by examination of the blood and urine, in both acute and chronic allergic states in human beings.

But, as Dale insists, the liberation of histamine will not account for all the symptoms and disturbances that occur in anaphylactic shock and allergic states. Thus the diminished coagulability of the blood, which is constantly found during the anaphylactic reaction in all animals, is not produced by histamine, but is a result of hepatic damage by various toxic substances. Dale points out that this fact alone suffices to show that constituents of the liver-cells other than histamine are liberated. He says further that "it is unlikely that the histamine, which the liver must pour into the general circulation under such conditions, will be free; it is more likely to be involved in colloidal complexes with the other cell-constituents."

Some recent experiments by Manwaring and his co-workers [8] on dogs are probably of great significance in this connexion. Manwaring, in his earlier experiments, showed that, if the liver of a sensitised dog be completely excluded from the circulation, injectio of the antigen into the blood stream has little or r effect, although histamine under such conditio produces its usual response in small blood-vesse and plain muscle. Manwaring concluded that t symptoms of anaphylactic shock in the dog were d to an anaphylotoxin produced in the liver, and havi a histamine-like action. He has since shown transplantation experiments that, as smooth musc structures can be actively immunised against t anaphylotoxin, the latter must be regarded as secondary antigen, "presumably of protein natu This substance is conceivably a denaturisati product of the primary antigen, either explosive formed from the injected toxic dose of the speci foreign protein, or explosively liberated from storehouse in the hypersensitive liver. In the latt case it would represent a denaturisation product the sensitising dose." Further experiments [9] co firmed this conclusion, which is "that mark chemical alterations take place in specific antige when injected into the animal body, and that ma of the essential immunologic adaptations are to t resulting denaturisation products (secondary antige rather than to the primary antigens origina injected. If this conception of immunological adap tion is correct, it would indicate that there a numerous immunological processes, and presumab numerous specific antibodies, that cannot be demo strated by current serological methods."

If these experiments of Manwaring are applicable human beings, they raise a very important question namely, whether in some allergic states the substa responsible for the symptoms, partially at any ra is not a product of tissue damage, resulting from t action of primary antigens on sensitised cells, p ticularly those of the liver, and acting as a seconda antigen. That sensitisation to the products damaged tissue may occur seems certain. Whitfield has recorded cases of trauma with bruising but witho breach of skin surface, in which a generalis erythemato-urticarial rash, resembling that of ser disease, appeared ten days after the injury, interval that corresponds to the incubation per of serum disease. One of us (H. W. B.) has observ similar cases, and an eruption of the same kind r infrequently follows amputation of the breast, which there is likely to be considerable extravasat of blood. All dermatologists are familiar with ca of chronic eczematous dermatitis of one area of skin, usually on the leg, in which, either after application of some irritant, or from trauma violent scratching, symmetrical eczematous pate appear on parts of the skin widely distant from area primarily affected. In such cases th presumably develops a general epidermal sensiti tion to products of tissue damage absorbed fr this area.

In some cases of allergy, it is true, spec sensitisation to a primary antigen exists, and symptoms occur only on contact with that antig As an example we may cite certain cases of e sensitiveness, manifested by acute urticaria occurr immediately egg is eaten, sometimes even when is taken only into the mouth. In such patie egg-antigen may be the sole cause of the urtica but instances of a single and specific susceptibil are the exception. In most cases of chronic urtica in the prurigos, in dermatitis herpetiformis, infantile eczema, and in many cases of spasmo rhinorrhœa and asthma it is impossible to disco any one specific cause for the attacks; yet, as been seen, such persons are so sensitive to min

oses of the proteose, isolated from their own urine, hat it must contain the antigenic substance. Is it ot likely that this substance is, so to speak, nanufactured on the premises, a product of their wn tissues? Apart from the experimental work of Ianwaring, the evidence we have obtained from iochemical investigations of the blood and urine in hese allergic patients points to the liver as the primary ite of tissue damage. We may, in fact, regard ensitisation of the liver-cells as being the essential actor in the cases we have in mind, and it is probable hat the primary antigens, to which the liver-cells re sensitised, are multiple, so that various foods and heir derivatives or bacterial toxins may excite the roduction by the damaged liver of the actual ubstance responsible for the symptoms. This ubstance, in our opinion, is excreted in the urine, nd contained in the proteose. In certain acute and hronic infections, also, the symptoms may be caused, ot by the direct action of the infecting organism on he structures affected, but by a substance produced s a result of tissue damage by the organism. Many ases of rheumatoid arthritis, for example, can erhaps be explained in this way. The primary ntigen may be a streptococcus or other organism, ut the arthritis might be an allergic reaction towards secondary antigen derived from the action of the ganism on the patient's tissues.

Therapeutic Considerations.

Method of Therapeutic Application of Urinary roteose.—As one is dealing with a chemically pure substance of unknown potency, it is always ecessary to ascertain the reaction of the patient the different dilutions before any therapeutic jections are given. This is done by making idermal tests on the patient with the different lutions. If, for instance, the 1/10,000 dilution is intly positive, and the 1/100,000 is negative, a all intradermal test with 0·025 c.cm. of the 1,000,000 dilution can be made. If this results in faintly positive reaction, the strength is suitable r the preliminary injections. We give gradually creasing doses intradermally, and sometimes sub-taneously, once a week, but time alone will show hether this method gives the best results. If care not taken with the dosage, the patient may react an over-dose by an acute outbreak of symptoms. e have found, however, that positive epidermal d intradermal tests are more likely to be found in patients with recurrent acute manifestations of ergy—e.g., urticaria, certain forms of asthma d of prurigo, dermatitis herpetiformis, and light-nsitisation of the adult type. In chronic conditions thout acute exacerbations, such as psoriasis, they ay be negative, but this does not necessarily imply at a therapeutic effect will not result from injections the proteose. It is in those diseases in which sitive tests are most commonly obtained that acute actions are likely to follow the injection of too ge a dose.

In this paper the methods and results of treatment ll be considered only in patients with cutaneous mptoms. The dermatological conditions for which have given injections of proteose are urticaria, geioneurotic œdema, prurigo of the simple type, the rurigo of Besnier, dermatitis herpetiformis, psoriasis, d light-sensitisation of the adult type. It should noted that some cases classified as prurigo of the mple type should more strictly be labelled eczema-rurigo, and that most of those with Besnier's prurigo l eczematisation, partly no doubt as a result scratching, and either were or had been subject to asthma and paroxysmal rhinitis. One of the patients with psoriasis was first seen with a severe generalised exfoliative dermatitis of six months' duration; her history suggested that it was a complication of psoriasis and this was confirmed subsequently. Our aim has been to present a fair estimate of the value of proteose injections in each of the conditions under consideration; some points of especial interest in certain individual cases will be emphasised. The majority of our patients received dietetic and internal treatment in addition to the injections, but some were purposely given these alone, and among them may be numbered our most satisfactory results.

Urticaria.—Nineteen cases of chronic urticaria and angeioneurotic œdema, all of them of long standing, have been treated in hospital or private practice over a sufficient period of time to allow of conclusions being drawn. In every case dietetic and internal treatments of various kinds had been previously given, and in a few of them other methods of desensitisation had been attempted. Some patients were extremely sensitive even to minute doses, each injection at first provoking an acute attack. The results, as far as we can judge to date, have been very favourable. Sixteen are now entirely free from attacks. In some this result was achieved by a few injections only, in others after two or three months' treatment.

Simple Prurigo.—Thirteen cases have been treated, nine of which are now practically free from itching. One had already become almost free from itching under suitable dietetic and internal treatment before the injections were begun, and cannot therefore be considered. Two were treated successfully by the injections alone, without other treatment. In one, after initial improvement, there was a relapse, and the patient was compelled to go abroad on business. Six cases deserve special mention, as they were particularly severe and intractable and had received expert treatment by other methods before coming under our care. In these we consider the injections were chiefly responsible for the satisfactory results obtained.

Besnier's Prurigo.—The characteristics of this form of prurigo and its frequent association with ichthyosis, asthma, hay-fever, and urticaria have been described in a previous paper.[1] It is clear that most of these patients have an inborn and often hereditary tendency to become sensitised to various antigens, and their life-history is one of repeated or chronic allergic manifestations. It is of interest that a positive van den Bergh reaction of the biphasic type is obtained in a high proportion of cases, even during periods of relative freedom from symptoms. The effect of injections of proteose in these patients has been of great interest. They have all been highly sensitive, even to very small doses, and in several instances severe asthmatic attacks have been provoked, although they had been free from asthma for months or years. It is well known that it is in these cases especially that the phenomenon of alternation of symptoms (*alternances morbides* of Brocq[11]) is met with; for example, when the prurigo or eczematisation is severe the patient is free from asthma, and vice versa. This is by no means constant, for both symptoms may be present concurrently, but on the whole it may be said that the cutaneous and visceral manifestations of allergy tend to alternate.

The initial effect of intradermal injections of proteose appears to be to desensitise the skin, and it is therefore not surprising that, as this improves, a latent visceral symptom, such as asthma, is provoked

If, however, the injections be continued in very small doses—and we think it advisable to give them after a while partly intradermally and partly subcutaneously—the asthmatic attacks cease. With four exceptions this group of patients has received dietetic and internal treatment in addition to the injections, but most of them had been under such treatment for months or years before the injections were begun, and we can therefore state definitely that these, provided the dosage be very carefully controlled, have proved of great value. Moreover, one of the exceptions referred to above—a patient with ichthyosis, eczema, prurigo, and asthma, who had attended many clinics for 18 years—was purposely treated with injections only, and the result has been very striking. Fourteen cases have been treated by the injections; all of them suffered or had previously suffered from asthma, in addition to their prurigo. It is impossible to claim cures in this group of patients, owing to the liability to relapse even after long periods of freedom from symptoms, but in five out of our 14 cases the injections have been discontinued for the past three months, during which time the patients have been comparatively well. The remainder are still under treatment, and are all steadily progressing. An interesting and important observation that we have made in this group is that in those who were ichthyotic the injections have produced a visible effect on the texture of the skin as a whole, so that in some, apart from the condition of the palms and soles, it would be difficult now to recognise the ichthyosis.

Dermatitis Herpetiformis.—In no condition has the effect of proteose injections been more certainly demonstrated than in dermatitis herpetiformis. Nine cases have been treated. One very severe case was given injections only and is free from his eruption at the time of writing. The remaining cases had all received various treatments previously, including dieting, arsenic, auto-hæmotherapy, intestinal vaccine (Danysz), and peptone injections. It can be confidently stated that no other method of desensitisation employed by one of us (H. W. B.) in dermatitis herpetiformis has given results comparable to those we have obtained with proteose injections. Four of these patients had for months relied on arsenic, and in two there were signs and symptoms of arsenical poisoning. On omitting the arsenic a severe relapse of the eruption occurred, but they are now practically well, although it is three months or longer since the injections of proteose were concluded.

One female patient deserves special mention, as she has been under observation by one of us for several years. When first seen the eruption was very severe, the skin was deeply pigmented—partly from arsenical medication—and harsh; she suffered from chronic dyspepsia and obstinate constipation, she was wasted, and lived the life of a semi-invalid. She improved considerably on a carbohydrate-rich but practically vegetarian diet, with injections of an autogenous fæcal vaccine. Later peptone was given by intravenous injection, and subsequently courses of auto-hæmotherapy; these and the addition of glucose to the dietary led to still further improvement both in her general condition and in the eruption, although she was still subject to periodical exacerbations. In November last, injections of a 1/1,000,000 solution of her urinary proteose were commenced and were at first followed by fresh outbreaks of the eruption, but she is now almost entirely free; she has gained several pounds in weight, and the change in her general appearance and the texture of her skin is remarkable. She herself is convinced that the injections of proteose have been responsible for more rapid improvement than anything else.

Psoriasis.—In the majority of cases of psoriasis, treated by us with injections of proteose, the eruption has been associated with rheumatoid arthritis of varying severity (arthropathic psoriasis). In these patients, without exception, a striking feature has been the susceptibility of the affected joints even to minute doses. An injection of 0·1 c.cm. of a 1/1,000,000 dilution is apt to provoke a sharp focal reaction in the joints, with a general but transitory feeling of malaise. The results of treatment in psoriasis arthropathica and in rheumatoid arthritis uncomplicated by psoriasis, have been very encouraging, but the effect has been more noticeable on the arthritis than on the psoriasis. In the few cases of psoriasis, unaccompanied by arthritis, so far treated by this method, the results have been disappointing on the whole, although two cases of generalised exfoliative dermatitis, occurring as a complication of this disease, did well.

Glucose Therapy.

In our earlier paper on allergy [1] we ascribed the therapeutic value of glucose chiefly to the fact that it provides the liver with a rapidly assimilable source of glycogen, which is essential for many of its recognised functions. Further observations have tended to confirm this view. O'Neill, May, and Manwaring have shown that "glycogen disappears almost quantitatively from the canine liver during the first 15 minutes of anaphylactic shock." Zunz and La Barre [13] found an initial hyperglycæmia in guinea-pig anaphylaxis, and McGuigan and Ross [14] a reduction in liver glycogen during peptone shock. This would suggest that the liver-cells utilise glycogen in their antitoxic function against antigenic substances, or, put in another way, that an adequate source of glycogen protects the liver-cells from damage by such substances. It is significant in this connexion that in some of our cases we have found that the proteose excreted while the patient was taking large quantities of glucose, gave negative cuti-reactions, but that, after omitting the glucose for a time, we obtained a proteose which produced positive reactions.

In conditions such as chronic urticaria, pruritus of internal origin, the prurigos, the allergic type of infantile eczema, and certain forms of asthma, the patient is liable to paroxysmal crises, usually nocturnal, which are comparable to repeated minor attacks of anaphylactic shock, and it is probable that these deplete the liver-cells of their glycogen-content so that their glycogenic secretory function is constantly being subjected to an unnatural stimulus. This would explain the rationale of the carbohydrate-rich dietary, with additional glucose or lactose, which clinical experience has proved of value in these cases. We think it important that for therapeutic use the pure powdered glucose should be prescribed in preference to the impure glucosum B.P., and that it should be given in one or two large tumblers of water on waking and at bed-time as well as, if necessary, during the day.

Summary and Conclusions.

1. The preparation and chemical properties of a substance, excreted in the urine and responsible for the ether-reaction, to which reference [2] was made by one of us (G. H. O.) in a previous communication, has been described. This substance, which we have termed urinary "proteose," is of complex composition.

2. Although present in small quantity in the urine of persons apparently in average normal health, it is found in relatively large amounts in acute and chronic microbial infections and admittedly allergic states, and in various other unsuspected or manifest conditions of ill-health. In allergic diseases it would appear to contain the specific antigen to which the symptoms are due.

3. The course and urinary findings in a case of serum sickness are detailed together with experiments designed, according to the Prausnitz-Küstner method, to establish the presence of specific antigen in the urinary proteose.

4. The significance of the proteose is discussed in relation to experimental findings in animal anaphylaxis, and the view is put forward that in chronic or recurrent allergic states, in which the symptoms cannot be ascribed to hypersensitiveness towards one or more known specific antigens, the antigenic moiety of the proteose may be a secondary antigen, produced by the sensitised liver (and possibly by other tissues) on contact with diverse primary antigens. In this case it would correspond to the anaphylotoxin of Manwaring. It is suggested that the manifestations of certain chronic diseases may be caused by sensitisation towards such secondary antigens.

5. The results of the therapeutic application of urinary proteose, in certain diseases of the skin, by means of intradermal and subcutaneous injections of it in high dilution are recorded. The rationale of glucose therapy is also discussed.

In conclusion, it may be said that the importance of urinary proteose lies in the fact that it is a definite substance, which in some acute and chronic diseases appears to contain the specific antigen upon which the symptoms depend, and can therefore be employed for specific desensitisation in measured doses. As a French colleague has put it: "The proteose provides us with a white powder, which is the long-looked-for link between the glass of milk and the colloïdo-clasic crisis."

BECCLES WAR MEMORIAL HOSPITAL.—At the annual meeting of this institution it was stated that of every shilling of income patients' payments provide 4¼*d.*, the contributory scheme 3¾*d.*, subscriptions 2½*d.*, and endowments 1½*d.*

PAYING PATIENTS AT BIRMINGHAM.—The annual report of St. Chad's Hospital, Birmingham, the primary function of which is to provide expert medical and surgical treatment for persons of moderate means, covers the 12 months to March last. A certain quantity of radium is now available, and there has been a renewal of general equipment. There were 930 in-patients, the largest proportion of whom (324) suffered from affections of the ear, nose, and throat. A labour ward and a nursery have been equipped, and the hospital is now relieving the pressure upon one of the voluntary hospitals by admitting as in-patients who are able to pay fees in accordance with the existing scale. The committee suggest the desirability of some simple system of insurance for paying patients; they believe that a premium of £1 to £1 5*s.* per individual would be adequate. The hospital is prepared to treat patients insured by an outside body on the following scale, irrespective of the kind of treatment required: 10 guineas and 1 guinea for each day's stay, with an additional charge of 10 guineas for a major operation.

PERMANENT HEMIANOPIA IN MIGRAINE AND SUBARACHNOID HÆMORRHAGE.

BY W. J. ADIE, M.D. EDIN., F.R.C.P. LOND.,

PHYSICIAN, CHARING CROSS AND THE ROYAL LONDON OPHTHALMIC HOSPITALS; PHYSICIAN TO OUT-PATIENTS, THE NATIONAL HOSPITAL, QUEEN-SQUARE.

I HAVE found no reference in medical writings to permanent hemianopia or other hemi-defects in migraine, migraine epilepsy, and spontaneous subarachnoid hæmorrhage. I think the cases that present them are worthy of record, because they are not very rare, they cause difficulty in diagnosis, and they seem to me to supply evidence that must be considered in discussions on the nature of the cerebral disturbance in migraine, on the relation of migraine to epilepsy, and on the relation—I think it is an intimate one—between migraine and spontaneous subarachnoid hæmorrhage.

Description of Seven Cases.

CASE 1.—Mrs. A., aged 30, has had attacks of migraine for 11 years. The headache is preceded by zig-zag lights, sometimes on the right, more often on the left side. Two years ago, after a severe attack beginning with lights on the left side, she found that she could not see things clearly on this side. A few weeks later she had a fit and was unconscious for three hours. At the beginning of this year Mr. F. A. Juler found that she had a large left-sided "para-central scotoma of hemianopic type." This persists unchanged. There are no other signs of disease in the nervous system or elsewhere. She has had no more fits; the attacks of migraine have been less frequent and less severe since she began to take luminal a year ago.

CASE 2.—Mr. B., aged 31, has had migraine since the age of 20; a golden rain on the right or left side, sometimes first on one side and then on the other, is followed in about ten minutes by a headache; in some attacks he feels a creeping sensation in the right or left arm. Six years ago he began to have attacks in which "a flushing sensation rises from the stomach to the head"; "he stares and loses himself; he goes right off." Three years ago, after a bad headache, he found that he was blind on the left side and that the left arm and leg were weak. When I examined him first three years ago he had a complete left homonymous hemianopia, definite left-sided pyramidal signs, and some position loss in the left arm. The hemianopia remains unaltered; the other signs have almost disappeared. He is taking bromides and luminal regularly, but still has several attacks of migraine every month, also numerous "flushings"; in two of these he lost consciousness.

CASE 3.—Mr. C., aged 49, suffers from migraine (duration not known); his headaches are preceded by fortification figures; on three occasions during the last 12 years he has had an attack in which the whole of the left side became limp for a few minutes, without loss of consciousness. At long intervals, during the same period, he has had four attacks in which a feeling of numbness in the groins passed slowly upwards to the head; in two of these attacks he lost consciousness for a minute or two, in one for half an hour, and in another for four hours. Three months before he came under observation he felt dizzy and noticed that he could not see things on his right side. He was admitted to the National Hospital, Queen-square, under the care of Dr. Hinds Howell. Examination revealed nothing abnormal except a right homonymous hemianopia.

CASE 4.—Mr. D., aged 26, has had frequent attacks of migraine for seven years. Everything goes misty for about ten minutes, then he gets a headache usually on the right side. Five weeks ago, while at breakfast, he had a "collapse"; it began with misty vision on the left side and pins and needles in the left arm; something rushed from his stomach to his head; he felt very queer and slid down from his chair; he did not lose consciousness, but he had to be assisted to bed. He had a severe headache all that day; during the day he noticed that he could not see things on his left side. A month later Mr. Adrian Caddy mapped out a complete left homonymous hemianopia which just spared the fixation-point. This persists. A complete investigation, including an examination of the cerebro-spinal fluid, revealed nothing else abnormal.

CASE 5.—Mr. E., aged 28, began to have headaches preceded by flashing lights at the age of 13. After one of his early attacks he noticed a persistent black shadow in

the outermost part of the left field of vision; it was there when he covered one or the other eye. Thereafter for about three years he had no more attacks, but the shadow remained. Since the age of 17 he has had an attack about once a month; while the headache was on, and for about half an hour afterwards, a greyness filled the remaining normal portion of the left field. Three weeks ago while at work he saw "a sparkling spangling blur" on the left side for about five minutes; this was followed by the most severe headache he has ever had; it lasted half an hour; after it had subsided he went on with his work; he then found that he could not see things on his left side. He had another headache four days later, otherwise he has felt well. He was admitted to the National Hospital three weeks after the severe attack: investigation, including an examination of the cerebro-spinal fluid, revealed nothing abnormal except a complete left homonymous hemianopia which divided the fixation-point.

CASE 6.—Mr. F., aged 35, has had attacks of migraine for ten years. After one of his early attacks he "lost the sight on the left side" for several days. During the last year he has had three attacks in which the right arm and leg became helpless and numb; this followed dimness of vision, once on the left side, twice on the right, and was accompanied by a feeling of pins and needles which spread from the right hand to the whole of the right side. On two occasions, several days after these attacks, I found a definite extensor response on the right side. While he was in the National Hospital in an interval between attacks the plantar response on the right side was flexor or doubtful. Otherwise there were no abnormal signs.

CASE 7.—Mr. G., aged 31, came under observation for left homonymous hemianopia; this was noticed two years ago, when he went to work after being in bed for three days with severe headache and vomiting. Fourteen years ago he had an illness which was diagnosed as meningitis. His neck was stiff, and he had a very severe headache for two weeks. During this illness "bloody fluid was drawn from the spine with a long needle." The headache on this occasion was "just like the one when the sight went." Seven months ago he had two fits with ten days interval between them; they came on without warning; he lost consciousness, was convulsed, and bit his tongue; they were not preceded by a headache; he recovered completely in an hour or two.

Six days after the onset of the visual trouble Mr. C. L. Gimblett found a complete left homonymous hemianopia which just spared the fixation-point. Eighteen months later the same observer found that some recovery had occurred in the central part of the fields only. When I saw him at this time I found nothing abnormal apart from the field defect, and reported that I had "little doubt that he has a congenital aneurysm that leaks from time to time."

Comment.

I shall not attempt to discuss here the bearing of these cases on the problem of the nature of the cerebral disturbance in migraine and the relation of migraine to epilepsy, but I wish to amplify, very briefly, my statement that there is an intimate relation between migraine and spontaneous subarachnoid hæmorrhage. This conclusion is based on the following set of observations:—

Migraine with classical symptoms of long duration is sometimes complicated by homonymous hemianopia and other hemi-defects, usually left-sided. In these cases, as in uncomplicated migraine, the visual hallucinations appear sometimes on one side, sometimes on the other, but much more frequently on the left side; non-visual sensory hallucinations sometimes precede the headache in cases that ultimately have hemianopia.

Patients with a long history of migraine and epilepsy may, as I have shown, come before us with permanent hemianopia and other focal signs. These may appear (*a*) after an attack of migraine, (*b*) after an attack in which consciousness is lost, (*c*) after an attack unlike these—e.g. with "dizziness" only.

Patients with an exactly similar history may have subarachnoid hæmorrhage. An example of this has so far eluded me, but Symonds[1] has described the case of a man, aged 37, who, "having for 26 years been subject to attacks both of epilepsy and migraine, but otherwise in good health, had an attack of subarachnoid hæmorrhage from which he made a complete recovery." The symptoms in spontaneous subarachnoid hæmorrhage are usually those of diffuse cerebral irritation or compression, but signs of a unilateral focal lesion may be present in the acute phase, focal signs may persist after an acute phase with signs of diffuse meningeal irritation, and a hemi-defect—e.g., hemianopia—may appear suddenly with no more general disturbance than a headache in a person who is known to have survived an attack of subarachnoid hæmorrhage in the past.

Migraine is a not uncommon precursor of spontaneous subarachnoid hæmorrhage. Goldflam[2] obtained a history of "true migraine" in five of 13 cases. Two of my cases—one proved by examination of the cerebro-spinal fluid, the other by autopsy ("congenital" aneurysm)—gave a long history of migraine with right- and left-sided hallucinations. Parkes Weber's[3] patient had migraine-like attacks, chiefly left-sided, for 30 years.

Thus we may expect to encounter the following observed sequences and combinations:—

Migraine, focal signs—e.g., hemianopia.
Migraine, focal signs, epilepsy.
Migraine, epilepsy, focal signs.
Migraine, epilepsy, subarachnoid hæmorrhage.
Migraine, subarachnoid hæmorrhage.
Subarachnoid hæmorrhage, focal signs, epilepsy.

At first sight it might appear probable that these are all due to the presence of a congenital aneurysm whose manifestations vary according to whether it gives rise to circulatory disturbance in its vicinity, short of bleeding, or leaks into the cerebral substance or into the subarachnoid space. It is certain, however, that no aneurysm is present in many of the young people who die of subarachnoid hæmorrhage, and I do not believe that the presence of this lesion is necessary for the production of the symptoms I have described. I am more inclined to conclude that some recurring disturbance of the cerebral circulation whose nature is at present unknown may, in minor form, manifest itself in symptoms for which migraine and epilepsy are convenient labels and, in major form, lead to infarction of the cerebral cortex or hæmorrhage into the subarachnoid space.

I wish to thank my colleagues, Mr. Caddy, Mr. Gimblett, Mr. Juler, Mr. Preston, Dr. Hinds Howell, and Dr. Denny Brown, for permission to refer to their cases and for their kindly assistance.

THE VASCULAR LINK BETWEEN THE PITUITARY AND THE HYPOTHALAMUS.

BY GREGOR POPA, M.D. BUCHAREST,

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF JASSY, AND ROCKEFELLER RESEARCH FELLOW, UNIVERSITY COLLEGE, LONDON;

AND

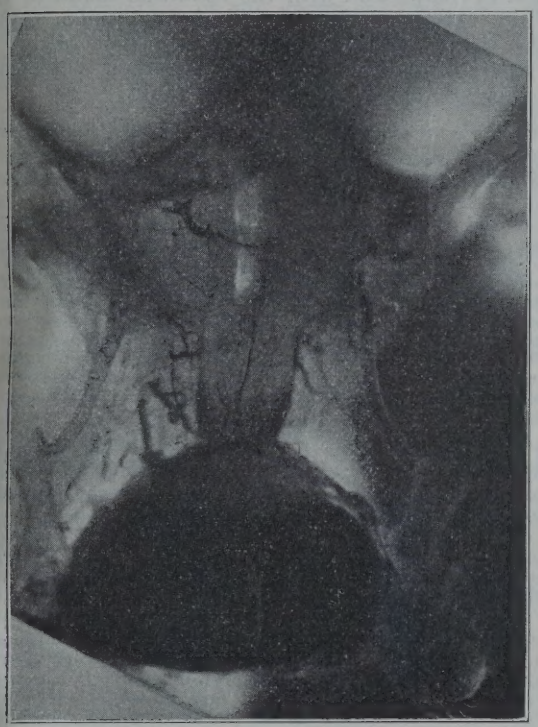
UNA FIELDING, M.B. SYDNEY,

DEMONSTRATOR OF ANATOMY AND LECTURER IN NEUROLOGICAL ANATOMY, UNIVERSITY COLLEGE, LONDON.

IN the Lister lecture published in the last two issues of THE LANCET, Prof. Harvey Cushing gives a masterly summary of the facts relating to the functional coöperation between the pituitary body and the hypothalamus. Hence a communication which we made to the Anatomical Society of Great

Britain and Ireland at University College on June 20th may be of some interest as affording new evidence in corroboration and extension of Prof. Cushing's argument. Pending the publication of our report on the presence of a hitherto unrecognised hypophysio-portal system of veins, we propose to call attention (by means of a photograph and an explanatory diagram) to the fact that there is a system of vessels which collects blood from both lobes of the pituitary and distributes it to the hypothalamus.

FIG. 2.



Photograph of the pituitary and hypothalamus (cleared in xylol) of another new-born child from the front, to demonstrate the naked-eye appearance of the hypophysio-portal veins in the stalk of the pituitary.

The secondary distribution net lies beneath the infundibular recess of the third ventricle, and there are indications that prolongations extend towards the nucleus paraventricularis and the nucleus supra-opticus.

Fig. 1 represents a graphic reconstruction of the hypophysis of a new-born child which was cut serially in sagittal sections (15μ thick) and stained by the silver nitrate method of Bielschowsky. Fig. 2 is a reproduction of an enlarged photograph of the pituitary and hypothalamus of another new-born child viewed from the front after clearing in xylol. It shows the blood-vessels represented diagramatically from the left side in Fig. 1 (in particular those on the stalk of the pituitary) with which this note is specially concerned, as they are revealed to the naked eye.

In Fig. 1, A is the anterior, and P the posterior lobe of the pituitary, and I the pars intermedia. The vessels numbered 1 are the hypophysio-portal veins arising from sinusoids (7) in the anterior lobe and from capillaries (16) in the posterior lobe. The branches which come from the pars intermedia are not shown in the diagram. On each side the internal carotid artery supplies to the gland a branch (2) which takes a spiral course (3) before opening into the sinusoids (7) from which the hypophysio-portal vessels of the anterior lobe arise. This artery from the carotid also gives branches (15) into the posterior lobe before it enters the anterior lobe. From the anterior lobe veins (4 and 5) leave the pituitary to enter the cavernous sinus (6). In this diagram the cavernous sinus is put below the pituitary merely for the sake of clearness, but obviously this is not its proper place.

FIG. 1.

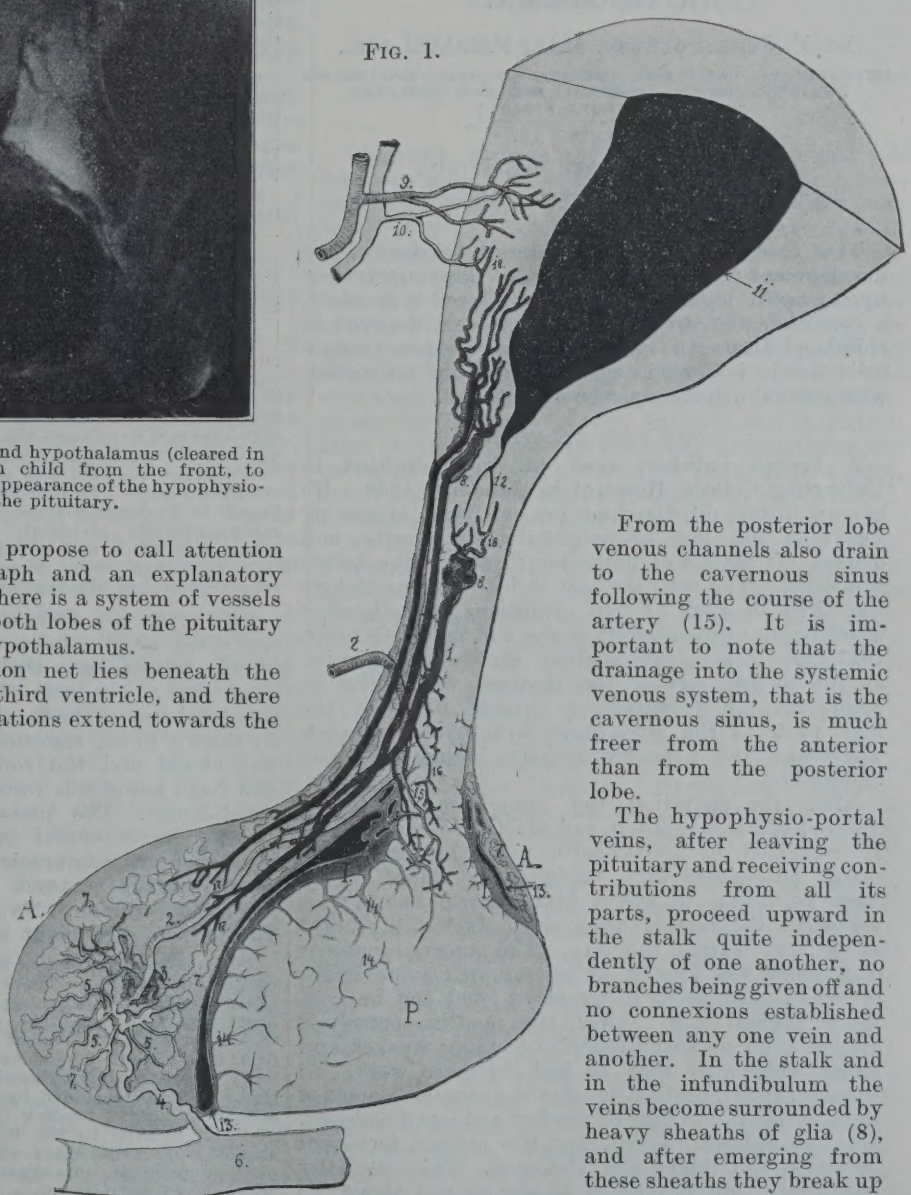


Diagram based on a graphic reconstruction of a series of sagittal sections (Bielschowsky stain) of the hypophysis of a new-born child, seen from the left side

From the posterior lobe venous channels also drain to the cavernous sinus following the course of the artery (15). It is important to note that the drainage into the systemic venous system, that is the cavernous sinus, is much freer from the anterior than from the posterior lobe.

The hypophysio-portal veins, after leaving the pituitary and receiving contributions from all its parts, proceed upward in the stalk quite independently of one another, no branches being given off and no connexions established between any one vein and another. In the stalk and in the infundibulum the veins become surrounded by heavy sheaths of glia (8), and after emerging from these sheaths they break up into a secondary distribution net (18), which is placed beneath the infundibular recess of the third

ventricle (11), and appears to have a definite distribution in the direction of the paraventricular and supraoptic ganglia of the hypothalamus, in which Collin has actually found the colloid substance such as we have found in the lumen of the hypophysio-portal veins. In addition to the arterial supply from the carotid (2) there are small arteries (9) proceeding to the infundibulum, and small veins (10) with a corresponding arrangement, which in some of our cases, although not in the one represented in this diagram, give branches which extend down in the infundibulum to reach the uppermost part of the pars tuberalis of the pituitary, such as Prof. Cushing's colleagues Dandy and Geotsch described in the dog (see THE LANCET, July 19th, p. 125).

Extensive prolongations (14) of glandular tissue from the pars intermedia and pars tuberalis intrude into the tissue of the posterior lobe of the stalk. The cleft (13) is exceptionally large in the young child in comparison with the condition found in the adult. Also the pars tuberalis extends much higher upon the stalk than it usually does in the adult.

Apart from these differences the other statements in this note apply equally to the adult.

CLINICAL AND LABORATORY NOTES

GASTRO-JEJUNO-COLIC FISTULA WITH ŒDEMA.

BY F. JOHN POYNTON, M.D., F.R.C.P. LOND.,

PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND SENIOR PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET;

AND

J. V. MACGREGOR, M.B. LOND.,

HOUSE PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

THIS case is of particular interest because of the development of a general anasarca. This supervened upon a gastro-jejuno-colic fistula produced in an adult, a condition akin to one which has been observed in childhood during the course of cœliac disease. Gastro-colic fistula is fortunately rare, and its association with general œdema must be exceptional.

THE CASE RELATED.

A French polisher, aged 46, was admitted to University College Hospital in January, 1930. He gave a history of diarrhœa for one year, increasing weakness and loss of weight for six months, and œdema of the lower limbs for three months before admission. The essential fact in his previous history was that in 1902 he had symptoms of indigestion which became progressively worse, and that in October, 1927, an X ray examination showed obstruction at the pyloric end of the stomach with delay in emptying. At operation a chronic ulcer of the first part of the duodenum with pyloric stenosis was found and a posterior gastro-jejunostomy was undertaken.

After the operation the man was completely relieved of his symptoms and started to gain weight. He remained in good health until January, 1929, when he contracted "influenza." Three weeks later he began to suffer from diarrhœa and this persisted, the bowels being open during the night as well as during the day. The average number of motions was four in 24 hours, with a maximum of seven. The appetite remained good and he kept to a normal diet. After six months persistent diarrhœa he noticed himself becoming weaker and losing weight, so that he had to cease work. In October, 1929 (nine months after the commencement of the diarrhœa), swelling of the feet and legs developed. He was ordered to bed, but the œdema increased involving the thighs and abdomen. This gradually improved; but as soon as he got up and about the swelling recurred.

Condition on Admission.—He was a small man, pale, asthenic, and wasted. The most prominent clinical sign was anasarca. There was œdema of both lower limbs and sacrum, free fluid in the abdomen, œdema of the bases of both lungs, and occasional swellings of the face. The heart was not enlarged but the sounds were faint. There were no signs of venous congestion. The pulse-rate was slow, 48 to 80. The systolic blood pressure was persistently low, varying between 90 and 118 mm. Hg. The temperature remained subnormal. The liver, spleen, and kidneys were not palpable. The examination of the urine showed no sugar or albumin.

Progress.—Œdema of both forearms and hands developed. It was noticed that the output of urine was low, averaging 20 oz. a day, but there was no reaction to diuretic drugs.

A urea-concentration test for renal efficency showed a normal percentage of urea in the urine.

A blood count was done and this showed:—

Total red cells	5,500,000	Polymorphs	79%
Hæmoglobin	76%	Lymphocytes	18%
Colour-index	0·7	Large mononuclears	3%
Total white cells	7,100		

The bowels were open, on an average, twice in the day and once in the night. The motions were liquid, dark grey in colour, acid in reaction, and had a foul smell. Culture gave a growth of bacillus only. At first he was treated with kaolin ʒi. t.d.s. As this had no effect on the diarrhœa which seemed to exhaust the patient, he was given a mixture of bismuth and opium. The motions were reduced to one in 24 hours but this was associated with vomiting which occurred once a day for three days. The vomit was then found to be fæcal, and on comparison with the fæces was macroscopically identical. A diagnosis of gastro-colic fistula was made and a radiographic examination showed that an opaque meal passed from the stomach into the transverse colon via the jejunum.

There was no alternative but *operation* and this was done by Mr. Julian Taylor after a preliminary blood transfusion. Owing to the poor general condition and œdema of the lungs, local anæsthesia was employed. The fistula was masked by adhesions so that a block resection was done. The stomach was closed and the continuity of both the small and large bowel was restored by separate end-to-end anastomoses. The mass removed showed a well formed gastro-jejunal opening. One inch distally the jejunum communicated with the transverse colon through a track one inch long, lined with mucous membrane. No jejunal ulcer could be seen. The patient died eight hours after the operation.

Post-mortem examination showed death to be due to acute broncho-pneumonia. There was marked wasting with absence of fat in all tissues; the weight was 7 st. 8 lb. The heart was small and the myocardium atrophied. There was atheroma of the great vessels. The liver was small, firm, and yellow. The spleen was atrophied. The kidneys were congested but otherwise normal. The veins of the limbs were not occluded by thrombosis. There were tough adhesions tightly binding the first part of the duodenum and the pylorus to the hilum of the liver. The healed scar of a duodenal ulcer was present in the posterior wall of the duodenum, immediately beyond the pyloric sphincter which was constricted to a diameter of 1 cm.

Microscopical examination showed myocardial atrophy, severe fatty degeneration of the liver, and that the kidneys exhibited no signs of nephritis. No gross cause for the œdema could be assigned.

COMMENTARY.

About 250 cases of gastro-colic fistulæ are reported in the literature. The common causes are carcinoma of the stomach or transverse colon, and jejunal ulceration following gastro-enterostomy. The occurrence of the latter group is increasing in proportion to the frequency that the operation is done. The exact percentage of the gastro-enterostomies which are complicated by fistula is uncertain, possibly about 2 per cent. Symptoms usually appear within two years of the operation. According to the accounts of Bolton and Trotter[1] and Verbrugge,[2] the main symptoms of this condition in order of frequency are: (1) diarrhœa; (2) vomiting of matter which is sometimes but not always identical with that passed by the bowel; (3) eructation of foul-smelling gases; (4) pain, which may be associated with jejunal ulceration or with subacute obstruction; and is more or less generally distributed over the abdomen; (5) wasting and weakness; (6) appetite remains good. To these symptoms may be added the tendency to fæcal vomiting when the diarrhœa is checked.

In this case diarrhœa and anasarca were the only symptoms apart from general weakness before the patient came under observation, and this indicates that any patient developing chronic diarrhœa after gastro-enterostomy should be investigated for a gastro-colic fistula. An absolute diagnosis may be made by employing the following tests:—

(1) Barium meal or an opaque enema.
(2) The giving of substances by the mouth, the excretion of which is timed—e.g., charcoal biscuits.
(3) The recovery from the stomach of dyes given as enemata.

The œdema in this case showed close resemblance to that which occurred in Central Europe during the late war. Many cases were reported from Germany, Poland, and Austria and Hungary in association with malnutrition. These cases of "war nutritional œdema" have been summarised by Maver.[3] Similar cases were reported from Egypt by Bigland,[4] who also noted the association of œdema with tropical diseases such as dysentery, cholera, and malaria.

The clinical picture exhibited by these cases of "nutritional œdema" was: œdema, usually of the feet and ankles, but also occasionally affecting the thighs, trunk, scrotum, face, and hands, with ascites and hydrothorax; emaciation; muscular weakness; anæmia; gastro-intestinal disturbances; a deficient diet; urine contained no albumin nor sugar; bradycardia; low blood pressure; blood count showed red blood cells 1·5 to 4 million, colour-index greater than one, lymphocytes 30 to 50 per cent.

Hume[5] and Chapin[6] report similar œdema in marantic infants suffering from: (1) Diarrhœa and vomiting. Difficult digestion and malnutrition. (2) Exhaustive conditions such as prematurity, marasmus, and extreme secondary anæmia. (3) In constitutional diseases: syphilis, tuberculosis, and pertussis. Poynton,[7] in a case of fatal cœliac disease, demonstrated that the ascites was not due to tuberculous peritonitis.

Various factors have been suggested as the prime cause in the cases of "nutritional" œdema. Retention of chlorides, lack of calcium and phosphorus in the blood, a diet lacking fresh vegetables, vitamins or protein, or a diet with excess of carbohydrates and water have been each considered the chief ætiological factor. The one common condition in all these cases is semi-starvation, the result of either lack of food or non-absorption due to gastro-intestinal disturbances.

This man was receiving an adequate mixed diet, but owing to the short circuiting of the small intestine, food could not be absorbed. The diagnosis was difficult until the fœtal vomiting occurred and this case brought home very forcibly the importance of a mysterious and persistent diarrhœa following upon a history of gastro-enterostomy for ulcer of the duodenum.

CHARCOT'S ARTHROPATHY OF THE SACRO-ILIAC JOINT.

BY HAROLD AVERY, M.B., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN, QUEEN'S HOSPITAL FOR CHILDREN; LATE MEDICAL REGISTRAR, CHARING CROSS HOSPITAL.

Charcot's arthropathy has been described as affecting most of the joints of the body, but I have been unable to trace a record of the sacro-iliac joint being involved. Micheleau,[1] Busche,[2] and Abadie[3] described deformities of the pelvis in tabes, but only as the result of arthropathy of the vertebral column causing changes from the postural attitude of the patient. Bramwell,[4] quoting an abstract from the *Centralblatt f. d. Grenzegebiete der Med. u. Chir.* (August 18th, 1904), says that the iliac crests may show considerable thickening and distortion, presenting a rough uneven surface, and numerous large exostoses. Neither Chipault,[5] in classifying 268 tabetic arthropathies, nor Gowers,[6] in numerous cases, found one in which the sacro-iliac joint was affected. I therefore place on record the following case:—

Mr. A. B., aged 45, a Levantine, consulted me in November, 1928. He was fairly weak, and complained of some sores on his back which had discharged for six months and were increasing in size and number. There were no abnormal symptoms except some irregularity of the bowels. There was a history of syphilis and gonorrhœa about 20 years previously, and in 1921, following a two years' history of pain and chronic obstruction suggesting trouble in the right iliac fossa, laparotomy was done by Mr. G. Gordon-Taylor at the Middlesex Hospital. Hyperplastic ileocæcal tubercle was found, and the terminal foot of the ileum, cæcum, ascending colon, and half the transverse colon were removed.

On examination there was, over the sacrum, a group of typical syphilitic punched-out serpiginous ulcers with yellowish slough in the base. Two thin, slightly pigmented, scars were present over the left tibia. The pupils were irregular in outline and unequal in size, but reacted to light and accommodation. The ankle-jerks were sluggish, the other reflexes brisk; there was loss of deep sensation in the calf muscles, otherwise no sensory disturbance. The Wassermann reaction was very strongly positive. No tubercle bacilli were found in the sputum, fæces, or discharge from the ulcers. Radiographic examination of the pelvis showed the gross hypertrophic and destructive changes in the left sacro-iliac joint, typical of Charcot's disease of joints.

Vigorous antisyphilitic treatment with iodides, mercury, bismuth, and neosalvarsan resulted at first

in great improvement in the general condition and later the ulcers healed completely. The patient is suffering no inconvenience from the pelvic lesion.

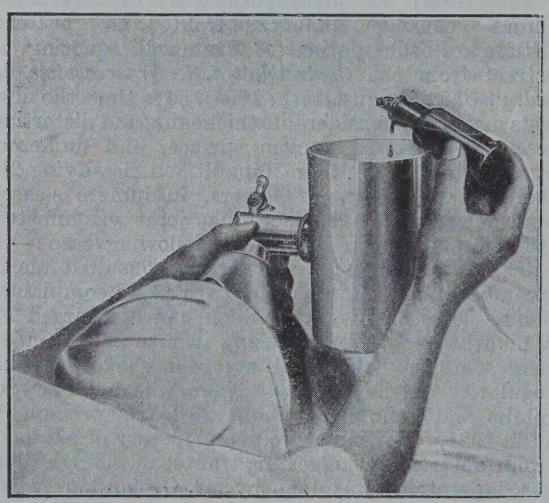
NEW INVENTIONS

AN IMPROVED OPEN ETHER INHALER.

THE inhaler shown in the illustration preserves the simplicity of the open method and increases its safety. The gauze-covered mask is placed in a container which is situated at the side of the face and never above it, the lower part of the container being a large well which traps any excess of liquid ether. It is thus impossible for the anæsthetic to get into the eyes of the patient, however freely it is used. The apparatus is made of metal (mostly aluminium), and is less than half the weight of an average Clover's inhaler. The whole apparatus may be boiled. Both the facepiece and the container may be rotated on the connecting tube, thus enabling the inhaler to be

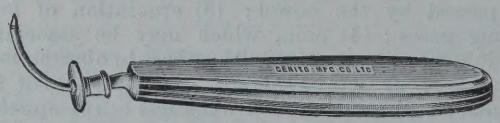


adapted to any position of the head while keeping the container in a vertical position. A tap is fitted for oxygen or carbon dioxide administration when required. The aluminium cage which supports the gauze does not require hinges or retaining clips for its covering, which are weak points in the ordinary type of mask. The component parts are riveted together, thus avoiding the small and flimsy soldered joints of the conventional wire cage. A pad of gauze is placed over the framework, and the whole is slid into the container, which is just large enough to hold it comfortably and just small enough to keep the gauze in position. The apparatus is reasonable in price, compact, and easily controllable with one hand, while there is no mechanism to get out of order, thus enabling the anæsthetist to concentrate solely upon the patient's condition and the surgeon's requirements. Messrs. Reynolds and Branson, of 13, Briggate, Leeds, are the manufacturers.

W. STANLEY SYKES, M.B. Camb.

NEW PATTERN LIPIODOL TROCAR AND CANNULA.

I HAVE been using a special trocar and cannula (see figure) which facilitates and simplifies the little operation for introducing lipiodol into the trachea for getting an X ray picture of the bronchial tree. The instrument is a small curved trocar and cannula mounted on a comparatively large handle at a suitable angle. Curved on the circumference of a circle of 16 mm. radius, the trocar has a sharp point which projects 3½ mm. from the cannula, which is 28 mm. long and 2 mm. in diameter, and has a fixed collar; the trocar is rigid and moves easily in the cannula. The large-sized and comfortable handle contributes



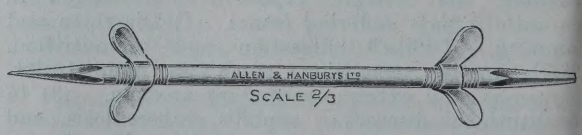
greatly to the control of the instrument and to the precision of the operation. One size only is needed, as the instrument is equally convenient for the largest and smallest trachea. As the result of the X ray examination depends on the quality of the skiagram obtained, which in turn largely depends on good technique, an instrument the use of which tends to secure freedom from coughing, crying, and spasmodic movements of the chest during the operation will go far towards securing with lipiodol a good representation of the bronchial tree. The curved trocar obviates flattening out of the trachea from antero-posterior pressure. In addition to the instrument described it is an advantage to have a tenotomy knife or a small double-edged knife for puncturing the skin.

The instrument was made for me by Mr. R. Schranz, and can be obtained from the Genito-Urinary Mfg. Co., Ltd., of 28A, Devonshire-street, W.1.

J. B. CHRISTOPHERSON, C.B.E., M.D. Camb., F.R.C.P. Lond.,
Physician, City of London Hospital, Victoria Park, E.

AN IMPROVED FORM OF STEINMANN'S PIN.

A MODIFICATION of Steinmann's pin, now in routine use in the orthopædic wards of St. Thomas's Hospital, is here illustrated. It differs from the standard pattern only in that it has a screw thread at each end on to which fits a winged nut. When cords are attached to the pin, the nut prevents their slipping off, and even allows the cords to diverge from the line of the



limb—often a great help in removing pressure from bony prominences distal to the point of insertion. The ordinary insertor handle is used with a screwing motion while the thread is traversing the bone, and the time taken therefore is slightly increased. Nitrous oxide anæsthesia still suffices for adults, while, as previously, gentle extraction requires no anæsthetic.

Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, are the manufacturers.

JAMES H. CYRIAX, M.R.C.S., L.R.C.P. Lond.

THE NEW MENTAL TREATMENT ACT.

CONFERENCE OF LOCAL AUTHORITIES.

On July 22nd and 23rd the Board of Control convened a conference of local authorities and visiting committees to discuss new administrative questions raised by the Mental Treatment Act, 1930. The chair was taken by Mr. L. G. Brock, Chairman of the Board of Control, and Mr. Arthur Greenwood, the Minister of Health, addressed the congress on the second afternoon. Mr. Brock emphasised the fact that, although for purposes of discussion the Act was regarded in sections, it was one coördinated piece of machinery.

At the first session, Dr. T. S. Good opened a discussion on "Out-patient Clinics," and described the origin and working of the clinic at Oxford. He argued for the establishment of clinics in connexion with general hospitals, and said that, although the admission-rate at the Radcliffe Infirmary and the general population of Oxford had increased, yet the number of mental patients chargeable to the city and the admission-rate at the mental hospital had appreciably diminished since the opening of the out-patient clinic. Reference to this discussion will be found on p. 247.

At the next session a discussion on "Voluntary Patients" was opened by Dr. Thomas Beaton, and at the final session there were short discussions on research, after-care, and the extension of the urgency order to rate-aided patients.

Treatment of Temporary Patients.

At the third session Sir Hubert Bond opened a discussion on Temporary Patients under Section 5. This section, he said, might almost be regarded as the pivot upon which the successful working of the Act rested. It abolished magisterial intervention for a period long enough to allow effective treatment; it abolished certification as an essential preliminary, and thus provided a direct stimulus to immediate treatment; it did more than any other legislative step in the last century to compose the differences between the medical and legal attitudes, and it created a new class of patient intermediate between the voluntary and the certified. The period allowed for temporary treatment was six months, extendable by the Board of Control to a maximum of 12 months. It was most important that no attempt should be made to strain the words of the Act to cover patients who were, in fact, unwilling and who ought to be certified. Since the visitation by a justice within a month of reception had proved unavoidable, it must be obeyed loyally. Sir Hubert urged everyone, however disappointed he might feel, to do his utmost to prove the Act a success, and to avoid awkward incidents. It was important that the patient should be seen by the official visitors in his bed or his own ward, and questions of procedure and status should never be discussed in his hearing. The condition covered by "the temporary status" often arose very suddenly, as in the puerperium or during toxæmia, but it might also arise in a patient already under care. If the patient were certified, there would be no call to change his status; if he were voluntary and lost his capacity to express his willingness to continue treatment, he must be discharged, certified, or placed on a temporary basis after 28 days. To avoid a feeling afterwards of unfair treatment, judicious chats with a voluntary patient were useful to inform him, without alarming him, of the possibilities inherent in mental illnesses. Nevertheless, difficult cases were bound to arise. The form of application was quite different from a certificate and the safeguards were not identical with those under the Lunacy Acts; they should, therefore, be studied carefully by medical officers. There was no restriction on the place of reception of the patient, except the approval of the Board of Control, but local authorities were under a very real moral obligation to provide active, up-to-date treatment. It was most important to nip in the bud the pernicious tendency to speak of "voluntary," "temporary," and "certified," as though these grades represented grades of severity of illness with corresponding inverse grades of recoverability and standards of accommodation and treatment. This tendency would kill the prestige of mental hospitals, mutilate their functions, and do incalculable harm to treatment. It was, however, part of the moral obligation of local authorities to provide for incipient and recent cases accommodation apart from chronic cases. In view of the new Act, there was an urgent need for the provision of an admission unit to all mental hospitals. Something in the nature of a bridge was needed between the home and the mental hospital; this "bridge" should have adequate laboratory facilities and, although it might serve as an observation centre, must emphatically not be regarded as a clearing-house. Its chief physician should be the physician in charge of the mental hospital. Its location was a matter for discussion, but undoubtedly the best place would be in close connexion with the local voluntary hospital.

THE PREPARATION OF THE APPROVED LIST.

The Chairman announced that the Board of Control, in order to perform its delicate task of drawing up lists of approved practitioners, had appointed a medical committee with Sir John Rose Bradford as President, and representatives of the Royal Medico-Psychological Association, the British Medical Association, and the Royal Society of Medicine as members. The Board would be represented by Sir Hubert Bond and Dr. A. Rotherham. He further pointed out that the section contemplated the reception of temporary patients into general hospitals which had been approved by the Board. This provision would have the great advantage of leading to a closer association between the general, voluntary, and mental hospitals, and between psychiatry and general medicine. It would be of especial value in cases complicated by obscure physical conditions, because the general hospital contained a medical team such as the mental hospital could not provide, and the study of these cases was likely to throw much light upon the relations between mental and physical disease. Moreover, the introduction of mental patients into teaching hospitals would give the student opportunities of clinical experience hitherto denied to him. The arrangements would not be uniform over the whole country and the change could not be made immediately, but it was important that the minds of all concerned should be focused at once on the project.

DIFFICULTIES.

Dr. W. F. Menzies mentioned a few of the difficulties of Section 5. In North Staffordshire the voluntary hospitals were not anxious to receive mental cases. He asked who were to make the recommendations, one of which called for a specialist's knowledge; there were not enough psychiatrists in the country to go round. It had been suggested that the medical officer of health's assistants should undertake the duty, and it was very hard to persuade a committee

that the mental deficiency expert was not necessarily an expert in curable mental disorders. It was also suggested that panel practitioners, who had given good service as recommenders of licensed houses, should give the second recommendation. This arrangement would obviously not work. The public assistance officer, again, had a magnificent record, but was not a medical expert. Dr. Menzies said that he would like to see the family doctor as one recommender and the medical officer of the mental hospital as the other. The mental hospital officer should, if possible, give the recommendation without going to see the patient, but it was doubtful whether a temporary patient could be legally brought to the asylum to see him. The second question was where the patients were to come. He was afraid that the place would be the "lunatic ward" of a workhouse. He asked local authorities, until special small collecting hospitals had been built or beds allotted in general hospitals, to bring patients straight to the mental hospital. He did not think that any more beds would be required, or that the local authorities would be put to any extra expense. Only 17 per cent. of the recent admissions to Cheddleton could possibly have been included as temporary patients. All needs would be supplied by the admission blocks now being built in all mental hospitals. He appealed to members of local authorities where the mental hospital officer was not a municipal officer not to be too much influenced by their clerks.

The CHAIRMAN remarked that Dr. Menzies had assumed that the approved practitioner must necessarily be something of an expert. This was not so. The clause providing for approval had been inserted by the House of Lords as a safeguard to the liberty of the subject; the recommending practitioner was only required to be someone of acknowledged standing. The kind of man required was that general practitioner of especial experience and capability who was normally called in by his colleagues to give a second opinion.

Dr. T. C. GRAVES observed that under the section a hospital might have to release the temporary patient who was not really fit to go out, but the responsibility did not then rest upon the hospital, any more than it did upon the general hospital in analogous conditions. The classes of patients who, although they were still seriously ill in mind and body, had volition, demanded serious consideration. If it was required to certify a patient he should first be removed from the mental hospital, except when acute mental symptoms dominated, and special reference had to be made to the Board. The aim of the section was to avoid certification, but in some cases the health of the patient demanded it. When patients recovered health they were not as a rule disposed to quarrel with the means by which they had recovered it.

MENTAL AND VOLUNTARY HOSPITALS.

Mr. F. L. BLAND, Chairman of the Suffolk Committee, spoke of the practical difficulties of coördination. It was for the layman to secure close coördination between the mental hospitals and the voluntary hospitals in the area. Most of the voluntary hospitals were short of money and situated in the middle of big towns—not the best place for mental patients. Their sites were very often not large enough for rebuilding. Financial assistance would be refused as the thin end of a bureaucratic wedge. Nevertheless, coöperation was vital not only with the large voluntary hospitals but with the small, in association with which it might be possible to establish out-patient clinics.

Dr. H. DOVE CORMAC thought that the proportion of non-volitional patients was much less than 17 per cent. He asked whether it was necessary to examine patients every day to see if they had recovered volition and, if they had, whether it was necessary to inform the Board or record the fact in any way at the start of the 28 days' interval. He asked whether the usual report had to be sent to the Board at the end of the first week after admission. He had found the general hospital to be, on the whole, inimical towards the mental hospital.

Dr. J. MIDDLETON MARTIN said that the Gloucestershire County Council had satisfactorily coöperated with and contributed to its voluntary hospital. He asked whether the omission of any provision for the local authority to send a patient into single care had been intentional.—The CHAIRMAN replied that it had been intentional, because no such need was anticipated.

Dr. J. F. DIXON foresaw the disappearance of the voluntary system, but recommended an expectant and hopeful attitude.

Councillor W. LOCKE, J.P. (Newcastle), said that the man in the street knew nothing of the advantages of the Act; he knew that his family did not come into the National Health Insurance scheme, and wondered if he would have to pay for their mental treatment if they were passed on through the public assistance committee to a general hospital or mental hospital. Publicity was essential.

Dr. R. W. GILMOUR advocated the voluntary system, because the patient's relatives nearly always desired to retain control. It would be unfortunate if matters could not be arranged with relatives independently of the Lunacy Act.

Dr. MARY BARKAS warned the meeting not to confuse the temporary patient with the borderline case, who was eminently suitable to be a voluntary boarder. Lay committees should realise that the non-volitional patient was essentially the acute case, and as disturbing to voluntary boarders as the most advanced and degraded chronic patient. Temporary patients needed the most expert nursing and medical attention; they were not cases for students to experiment on, or for junior house physicians to treat. They should not, for the sake of eye-wash, be denied the expert treatment which only a mental hospital could give, and accommodated in what would be very little different from the present workhouse infirmary observation ward. The ideal institution was perhaps a clinic such as the Maudsley, in close touch with a large general hospital, but this was only possible in very large centres, and could not cover the requirements of a scattered and poor community. She disliked the institution of visiting justices. She feared that if the mental hospital officer were the person to grant the recommendation he would always be regarded with suspicion by voluntary boarders.

Councillor Mrs. EVA HARTREE (Cambridge) said that the public could best be educated through voluntary educational societies. The only men's societies of the kind she could think of were the Rotary Clubs and the Y.M.C.A., but there were numerous institutions for women.

Dr. P. T. HUGHES recommended that the public assistance committee should start a neurological department in a convenient workhouse infirmary in consultation with mental hospital officers. Otherwise the county council could approach the general hospitals and be responsible for the cost of the new buildings.

Mr. S. J. F. MACLEOD, K.C., counsel to the Board, dealt with some of the legal points that had been raised.

REVIEWS AND NOTICES OF BOOKS

Old Age: the Major Involution: the Physiology and Pathology of the Aging Process.

By A. S. WARTHIN, Professor of Pathology in the University of Michigan. London: Constable and Co. 1930. Pp. 199. 15*s*.

The Creed of a Biologist.

Same author and publisher. Pp. 61. 7*s*. 6*d*.

THE appearance of a book on old age by a pathologist of the standing and experience of Prof. A. S. Warthin is naturally something to which we should look forward with a lively anticipation of sound observation and wise deduction. Nothing is, in fact, needed more in pathology than a careful analysis of the ageing process in man, based on the ascertained facts of morbid anatomy. Now that men and women live so long, medicine is concerned more and more with the reactions to injury of bodies which have passed their prime and are in one way and another already more or less decayed. We want, therefore, very much to know exactly how the body at 60 and at 90 differs from the body at 25 and, at the other end, why few people can play Rugby football after 30, and why it is remarkable that Tilden should win the lawn tennis championship at 37. Prof. Warthin's account helps us very little to understand these things, and, frankly, we find it disappointing. Of facts there are very few; spermatogenesis is dealt with in some detail, but for the most part we look in vain for the concrete results of Prof. Warthin's autopsy experience. We should be glad, for instance, to know the numerical basis for the statements on pp. 41–42 that the increase in the sizes of viscera between 30 and 40 are due to hypertrophy rather than hyperplasia. There is a strange inconsistency between the statement on p. 147 that all the examples of intrinsic senile death which Prof. Warthin has personally examined were due to myocardial atrophy and inadequacy, and that on p. 157, where he says "death in man results from the death of the central nervous system, which always dies first." On p. 82 he says "the functional curve for the central nervous system rises continuously from birth until about the seventieth year," and on p. 83 he affirms that at the time when senescence is first perceived "the only function curve that shows any decided decline is that of the reproductive function." He nowhere considers the capacity to do muscular work of a refined and coördinated kind—e.g., to run—as a function worth consideration, though there is no human capacity on which man depends more for his survival.

The book, as we read it, is not a serious contribution to pathology but a bright and readable exposition of the simple fact that old age is bound to come and cannot be avoided. It can be understood better if it is read in conjunction with another book which Prof. Warthin has recently published—"The Creed of a Biologist"—in which he preaches that the whole duty of man is to select a wife on the best eugenic principles, have three or four children, and bring them up properly. From that point of view the demonstration that tissues isolated by themselves in artificial culture are immortal, senescence being a function of the body as a whole, is immaterial, and Prof. Warthin brushes it on one side as meaningless.

Treatment of Chronic Arthritis.

By A. H. DOUTHWAITE, M.D., F.R.C.P., Assistant Physician and Physician in charge of the Massage Department, Guy's Hospital. London: Jonathan Cape. 1930 Pp. 127. 5*s*.

So much has been written on arthritis that it is refreshing to find a physician approaching the subject from a different angle—that is to say, with a full appreciation of the important part the surgeon plays in a condition which can be considerably relieved by appliances, manipulations, and occasional operations. The opening chapters are conventional, the sections on pathology, ætiology, and clinical features following the inevitable familiar course; a clear distinction is made between infective arthritis and rheumatoid arthritis. If every doctor read and assimilated this teaching, possibly healthy teeth and tonsils would not be so ruthlessly removed from obedient owners. Again, the division of rheumatoid arthritis into three stages is most useful, with a suitable line of treatment indicated for each stage. There can be no doubt that much harm is done by applying the same treatment to the condition, whether it be active, subacute or chronic, and incidentally the patient's sufferings may be much increased. In discussing treatment the author suggests that deep X ray therapy in the treatment of osteo-arthritis has possibilities that have not yet been fully explored. He suggests a method for applying thermal treatment which is little known but is well worth considering—namely, the painting on of layers of hot wax. For vaccines Dr. Douthwaite has little use, and he considers their administration unjustifiable in the absence of sepsis; in his view "probably the greatest objection to vaccine therapy is that it deludes the physician and patient alike into the belief that something active is being done for the disease, which in the meantime pursues its remorseless course."

Throughout the work notes are introduced on recent research into arthritis, and the reader is thus made familiar not only with modern methods of treatment but with the investigations being made on the biochemistry and pathology of the arthritides. This book can be warmly recommended.

Les groupes sanguins schêmas et applications pratique.

LA TRANSFUSION SANGUINE, TECHNIQUE ET INDICATION. Par PAUL MICHON, Médecin des Hôpitaux de Nancy. Paris: Masson et Cie. 1930. Pp. 120. Fr.16.

THIS small handbook is intended for the practitioner, and is not overburdened with historical or with theoretical considerations. The first portion is concerned with the blood groups, and describes the fundamental facts, the various agents responsible for agglutination, the methods of determining the blood groups, and their biological and medico-legal aspects. The author describes a simple method of testing on a slide, but advocates the use of stock sera of three groups, II., III., and IV., instead of the usual II. and III. The second portion of the book deals briefly with the practical side of blood transfusion—choice of blood donor, technique of the operation, the therapeutic action of transfusion, and

indications. There is also a short bibliography. It would scarcely be possible to compress the subject into a smaller space than this book, but within its limits the essentials are clearly described.

Handbuch der Ernährungslehre.

Vol. II. Spezielle Diätetik der Krankheiten des Verdauungsapparates; Part I., Magen. By CARL V. NOORDEN and HUGO SALOMON. Berlin: Julius Springer. Pp. 460. M.39.

THE title of this book is misleading, for it understates the scope and underestimates the value of the contents. Instead of being a mere treatise on the dietetics of gastric disease, the work is really a portion of a text-book of medicine in which the subjects are dealt with principally from the standpoint of treatment, but with due reference to the essential facts of causation and symptomatology. The section on gastric and duodenal ulcer, which takes up 50 pages, is a typical example. After a short but adequate summary of the ætiology of peptic ulcer, its diagnosis by X rays and chemical tests, and its symptoms, there follows a detailed description of the management of a case, from the time the patient consults the physician for pain or hæmorrhage, through the treatment of the florid ulcer by diet and medicines, until a successful result is obtained by medical or surgical means. Indications for operation, decision as to type of operation advisable, and the after-treatment of ulcer cases, whether operated on or not, are discussed. Gastritis, acute and chronic; alterations of secretion, whether of excess or defect; cancer; dilatation of the stomach, and those conditions classed as nervous dyspepsia, are dealt with in a correspondingly exhaustive manner. The book contains an excellent account of the present-day knowledge of the physiology of digestion in the mouth and stomach; and each section provides a bibliography of the standard works in the various European languages, together with recent papers incorporated in the discussion in the text. The book, which has a good index, will provide accurate and considered information for all workers in the subject of gastric disease.

A Manual of Diseases of the Eye.

Sixth edition. By CHARLES H. MAY, M.D., Consulting Ophthalmologist to the Mount Sinai Hospital, New York; and CLAUD WORTH, F.R.C.S., Consulting Surgeon to the Royal London Ophthalmic Hospital, Moorfields. London: Baillière, Tindall and Cox. 1930. Pp. 475. 15*s*.

THE first English edition of this book appeared in 1906, and since that date there have been more than a dozen reprints or new editions. The teaching is sound and the illustrations adequate, and yet the student who relies exclusively on the information to be derived from this work may have cause to regret that he did not supplement it by attending a good ophthalmic clinic where the teaching is quite up to date. Revision of a work that was quite adequate a quarter of a century ago is a very difficult task if it is desired to keep pace with recent advances in ophthalmology. To give two instances: rheumatism and gout, as well as auto-intoxication from the septic foci in the body are all mentioned as possible causes of iritis, but the student is not told that nearly all the cases that used to be attributed to the first two causes are now generally put down to the third. But in a later chapter, on the ocular manifestations of general disease, this very point is stated clearly in accordance with the modern view. Again, in the chapter on cataract the traditional account of the structure of the lens as consisting of nucleus and cortex is given. It is only in a separate chapter by Mr. Harrison Butler, written especially for this edition, on the slit-lamp and corneal microscope, that we find the modern discoveries of the nature of the lens structure described. Indeed, perhaps the most interesting parts of the book are the chapters specially written for its different editions. The late Mr. Devereux Marshall's account of Dr. Edridge-Green's theory of colour vision is the best to be found outside the latter's own writings; Mr. Sydney Browning's chapter on vaccines in ophthalmology is also excellent. The chapter on squint gives, as we should expect, a useful summary of Mr. Worth's personal teaching on a subject which he has made his own. We observe that in discussing the operative treatment of convergent squint he speaks disparagingly of the operation of recession of the internal rectus muscle by means of a suture, a procedure which, whether or not combined with an advancement, has been growing in popularity with many ophthalmic surgeons in recent years.

Chirurgie des os et des articulations des membres.

Par P. LECÈNE, Professeur à la faculté de médecine de Paris. Avec la collaboration de P. HUET, chirurgien des hôpitaux de Paris. Paris: Masson et Cie. Pp. 591. Fr.140.

THIS work was nearly finished when the outbreak of the Great War delayed its publication, and wisely deciding that his views and practice required modification in the light of his war experience, Prof. Lecène held it up for revision. The result is a treatise on the surgery of the bones and joints of the extremities which is in full accord with the most modern views and practice. The first section deals with the operative treatment of both simple and compound fractures. Operations for malunited fractures, which in this country at any rate constitute the major problems of fracture surgery, receive but scant attention. The section on osteomyelitis is admirably written, but that on bone tumours would have been much improved by illustrations. The fourth section deals with wounds of joints and operations on joints, and is undoubtedly the best in the book, both in text and illustration. The section on tuberculosis of bones and joints is unsatisfactory, since it is limited to operative indications and measures. The section on amputations is good; it includes a useful chapter on artificial limbs. Excisions are dealt with on orthodox lines. The last part of the work is devoted to the surgery of bone and joint deformities, and is far too short to do justice to such a wide subject.

The work makes no pretension to being a book on operative orthopædics, for it is deliberately limited to the operative treatment of bone and joint conditions. Within these limits it is very useful, and the author is to be congratulated on the fair manner in which he presents his own views and those of others on the problems concerned.

ST. PETER'S HOSPITAL, COVENT GARDEN.—Lady Ravensdale recently opened a new out-patients' department, pathological laboratory, and nurses' quarters. These improvements, and others in progress or contemplated, will cost £24,000.

THE LANCET.

LONDON: SATURDAY, AUGUST 2, 1930.

OUT-PATIENT CARE OF EARLY MENTAL ILLNESS.

THE Mental Treatment Act, 1930, which becomes law on the first day of January next year, marks a great advance in the attitude of the legislature to mental disorder. It throws upon local authorities and visiting committees many duties which have not hitherto been obligatory and some of which have actually been forbidden. The Board of Control therefore called a conference to discuss the new situation practically, for, as the Chairman of the Board pointed out, this is no time for vain regrets that the Act is not moulded nearer to the heart's desire of the psychiatrist. Compromises were inevitable if the Bill was to become law, and the duty of experts now is to cultivate the ground that has been gained and to educate public opinion so that further concessions may be justified in the near future.

Typical of the spirit of the advance is the clause which empowers local authorities to make arrangements for the treatment of out-patients, and on this the Conference heard many of the opinions reported in THE LANCET.[1] Hitherto, as Prof. G. M. ROBERTSON remarked, visiting committees and medical officers have been concerned with the care of the certified; in future they are to be responsible also—and even primarily—for the prevention and early treatment of mental disorder. To accomplish this task successfully two things are essential: the confidence of the patient and the coöperation of the general practitioner. As Dr. T. S. GOOD and Dr. R. W. GILMOUR pointed out, the patient is always terrified. He describes his fear as the fear of going mad, but is often unable to explain what this means. Behind it lies the fear of being "shut up." That fear must be expelled before anything can be done. For this reason the general consensus of opinion was in favour of receiving mental out-patients at general hospitals. Once they have seen the psychiatrist there and realised his power to help, they will gladly see him again elsewhere, even at a mental hospital. Often enough they will be quite willing to enter a mental hospital under his care. The out-patient department, as Dr. GOOD observed, is the source of the voluntary boarder. Thanks to the new Act, medical superintendents will no longer have the painful experience of having to refuse admission to early cases until they have become so much worse that they are certifiable. Dr. R. EAGER said frankly that he had found the old Act a great obstacle to the early treatment of mental disease. Another cogent reason for making the psychiatric clinic part of the general hospital out-patient department is that advice and treatment are there available for any part of that complex organism which the psychiatrist must never forget to view as a whole. A difficulty in rural areas is the distance that some patients have to travel to reach a large hospital. Sir WILLIAM LOBJOIT suggested the cottage hospital as a solution of this problem, while other speakers recommended that travelling expenses should be provided; in Exeter this is done out of a benevolent fund. To ensure the interest of the general practitioner Dr. GOOD advised the psychiatrist to go about among his professional brethren, while every speaker emphasised the importance of writing to doctors who send patients to the clinics, giving them a full report and full instructions. As Dr. A. A. W. PETRIE pointed out, the local practitioner wants to be told just exactly what to do with the mental cases that remain under his care, and, as Prof. ROBERTSON said, simple physical measures are often adequate treatment but will not be adopted unless advised by someone with authority and experience. In Worcestershire, according to Dr. P. T. HUGHES, the local profession is anxious for the establishment of clinics, while other speakers admitted regretfully that the practitioner was apt to be as suspicious and mediæval in his attitude as the laity. This difficulty, at any rate, is likely to die out, for the undergraduate of to-day is showing much interest in psychological medicine.

To local authorities the economic aspect of this problem is inevitably of great importance. The general opinion was best summed up by Sir HUBERT BOND, when he said that in all the realm of medicine no better value could be obtained for money than in the psychiatric out-patient clinic. For the establishment of a clinic nothing is needed save a waiting-room, a consulting-room, a doctor, and a nurse. The services of doctor and nurse should cost nothing, as they should be regarded as part of the duty of the staff of mental hospitals. The hospitals should be made to realise, said Dr. A. T. FORRESTER, that all that is asked of them is chaperonage. As soon as the clinic is established, however, the need for beds at once becomes apparent; these can be provided in mental hospitals if chronic cases are transferred to poor-law institutions under the Local Government Act, 1929, but an even better arrangement—most speakers felt—would be for the general hospital to allot beds to their psychiatric clinic. Many apparent objections to this scheme have been shown to be groundless by the experience of the Middlesex Hospital, where functional nervous cases, including even violent and suicidal patients, have been successfully nursed by the ordinary staff in the general neurological ward. Another great need of the clinic, and one involving small expenditure, is the social worker. Miss EVELYN FOX, emphasising the necessity for a specially trained and experienced woman, said that the Central Association for Mental Welfare is proposing to arrange for the provision of these helpers to local authorities. Finally, and most important of all, comes the problem of the personality and training of the psychiatrist. On that everything depends. Dr. J. R. LORD, pleading for better psychiatric education, said that patients had had far too much patting on the back and simple physical treatment.

[1] THE LANCET, July 19th, p. 137.

They required the most skilled psychological handling and in that way alone would the clinic prove a real saving of money. Without it the pessimist, who said that the numbers saved from certification would be small, might indeed prove right. Each new case needs about an hour for satisfactory examination, and it is impossible for half a dozen medical officers from the county mental hospital to serve clinics for the whole area. Birmingham University is hoping to provide a training centre in psychiatry for practitioners and any of the organised clinics will be glad to receive doctors for training, but there is undoubtedly an inadequate supply of reapers for the harvest which is ready. The handling of early mental disease is not a matter that can be learnt from books. While there must obviously be some who are unfitted for the work, Sir HUBERT BOND enunciated a great truth when he said that the man who wants to do it, but is appalled at the difficulties and his own inadequacy, is the man who should go ahead, for he will do well.

BACTERIAL VARIATION.

IN the early years of bacteriology bacteria were supposed to be extraordinarily variable and capable of a series of transformations which no one would believe in nowadays. The allegations that a bacterium was a stage in the life-history of a higher fungus or that it might change into an alga no doubt originated in imperfect methods and impure cultures. As a proper corrective and in the necessary insistence on a rigid technique opinion swayed too far, as we see now, in the other direction; even mild pleomorphism became suspect and every species was supposed to conform to a certain fixed set of characters. Bacteria became, indeed, about the least variable group of living things, which would be very remarkable if it were really the case, for they occur in larger numbers and multiply faster than any other animals or plants. This view did not, of course, actually represent the facts of observation and experiment, and in the last 20 years, since bacteriologists have attended to the matter and observed what they saw, it has been realised that bacteria vary freely in various directions in ways which are mostly ill-understood. It is timely that the last volume to be issued (Vol. I.) of the "System of Bacteriology," published under the auspices of the Medical Research Council, contains a critical survey of the subject by Dr. J. A. ARKWRIGHT, who has himself contributed so much to the elucidation of the variations of meningococci, dysentery bacilli, and the typhoid group.

Recognisable varieties fall naturally into two large groups: those which are temporary, due to the environment, and will revert to the normal standard as soon as standard conditions of life are resumed; and those which are relatively permanent and heritable. It is this second class which is of particular interest and importance. They arise definitely and more or less suddenly and they are not easily reversible; hence they are often called "mutants," on the analogy of the apparently similar genetic changes which occur in higher animals and plants. The term is not a good one in bacteriology and is best avoided, since by implication it connotes a chromosomal constitution which has not yet been seen in bacteria. Practically all the perceptible characters of bacteria are known to show these hereditary variations—the shape, flagella, capsule formation, the form of colonies on solid media, the mode of growth in broth, the fermentation of carbohydrates, the formation of indol, virulence, antigenic properties, and so on. The definition of a "species" is often difficult, as Sir FREDERICK ANDREWES points out in another chapter of the same volume, but there is no doubt that the criteria of differentiation are to be found in the assemblage of characters possessed by any bacterium rather than in any single quality. Any one of these characters may vary and several may vary together, but for all that there is no clear instance where variations have, as it were, changed one "species" into another. The plague bacillus hardly differs from the pseudotubercle bacillus except in its pathogenicity, and the two are quite likely variants of what is essentially the same thing; since, from the human point of view, one is important as a pathogen and the other negligible, they have been classed as two "species." But such cases are very rare and the study of variation has given no support to the idea that one kind of bacterium may be changed into another. The pseudotubercle bacillus may possibly be a non-pathogenic form of the plague bacillus, but the transformation of one into the other has never been observed. Practical considerations do, however, arise. The non-pathogenic variants known as "rough" forms are generally found to appear in old cultures under conditions where some form of degeneration would be, a priori, not unlikely; the virulent "smooth" forms are commonest in cultures recently isolated from the body. The change from smooth to rough has often been seen, that from rough to smooth much more rarely. But it seems quite likely that the rough type represents the wild or saprophytic form of the species, and that its acquisition of parasitic virulence is associated with the change to the smooth type. Hence we have the obvious possibility of the appearance of a pathogen apparently de novo. Some of the hereditary variations are adaptive in the sense that they are caused by and distinctly related to something in the environment; the typhoid bacillus, for instance, "learns" to ferment dulcite by growing on media containing dulcite. So we may suppose that the acquisition of the parasitic habit is caused by coming into contact with a specific live animal. And under certain conditions a change from rough to smooth has been observed in these circumstances.

Our only regret about Dr. ARKWRIGHT's account is that he has not enlarged upon the more general biological implications of his facts. Owing to their exceptionally quick multiplication bacteria form unique material for evolutionary studies, and this is only partly offset by the impossibility of examining a population individually. Still,

it seems that adaptive variation is among their possibilities ; if that is so, the effects of progressive selection become almost impossible to study. And the interesting consideration arises whether selection and adaptive variation are not really the same process.

THE FATE OF THE ROYAL VETERINARY COLLEGE.

THE position of the Royal Veterinary College, as revealed last week in the House of Lords (see p. 274), is a discredit to the nation. Lord HAREWOOD said, giving figures as well as facts, that many of the buildings were dilapidated and irreparable ; that the money available for acquiring the site, for rebuilding, and endowment was a sum which, even with the large assistance promised by the Government, would be inadequate ; that the chances of the College authorities raising the further sum needed, including the automatic increase of Government assistance, were hopeless ; and that unless a larger offer should come from the State further students could not be taken. In other words, he showed that the College would cease to exist when the curriculum of the existing students is completed. This is a state of affairs that seems almost incredible in Great Britain, and in connexion with the capital of the Empire. Our national claims for pre-eminence in the scientific breeding of agricultural stock are not in dispute, but none the less this important school for the appropriate training of veterinary surgeons is in peril of decease. For Lord DE LA WARR, as the mouthpiece of the Government, was unable to hold out any hope of increased assistance.

There never was a time in the history of medicine when veterinary study, whether in its widest or most detailed conception, was more directly allied to the science of medicine than to-day. It is unnecessary to point out how deeply and how broadly modern medicine, alike from the preventive and curative aspects, is allied to the right comprehension of the physiology and pathology of the animal world. Such an imminent threat to the progress of veterinary medicine is a matter that concerns the whole of the medical profession ; much medical and surgical research will be impeded, as will be the progress in different directions of public health development and the organised study of dietetics. At the Royal Veterinary College the students get a thorough clinical experience from the care of thousands of sick animals which are brought to the College for diagnosis and treatment ; and no other College can boast of equal facilities for enabling the students, as and when their equipment reaches the proper level, to take an active part in dealing with their animal patients. They have the opportunity to see, diagnose, and treat many obscure conditions in a way that is only possible at an institution which is the focus of large endeavours. The statistics of the operations performed with good result would make surprising reading for most people, while this average of success implies labour and resourcefulness that should be needless, because of compulsion to employ inadequate apparatus. Stock and special vaccines are regularly prepared at the College, there is prompt post-mortem examination of carcasses submitted for the purpose, and pathological specimens are daily reported upon. All this work is in successful course under poor conditions, proving that the Metropolis is a fitting centre for such activities, even when they are carried on without due equipment.

While setting out the hope that some way will be found of avoiding the disgrace to us all of allowing the College to remain in its present critical plight, it is pertinent to point out that its transference, for economical reasons, to a site in the country would not meet the case. Removal from a centre where large and variable clinical material is always forthcoming and where, if the money were provided, facilities for teaching and for research would be at their highest level, must be a retrograde step.

CANCER: A GEOGRAPHICAL SURVEY.

APART from the valuable statistical reports on cancer, of which the latest is summarised on p. 260, several memoranda have been issued with the object of transmitting to local authorities information collected by the Departmental Committee on Cancer of the Ministry of Health. Circular 1136, just published, differs from its predecessors in demanding instead of giving information. The Minister hopes that a more complete knowledge of the reactions between cancer and any local community may provide a basis upon which, after due consultation, to take local action. The tendency to delay seeking treatment until the opportunity of permanent relief has passed must be combated systematically. In the presence of cancer of those organs where an abnormality gives rise to some obvious sign or symptom the reasons for fatal delay, whether physiological, psychical, economic, or social, should be ascertained and met. In other organs, notably some of the internal organs, cancer does not at the onset give rise to signs which are easily recognisable, and here the chief prospect of good lies in securing improvement of the facilities for diagnosis. The treatment and nursing locally available for inoperable cases also requires consideration. As to the proposed methods of investigation, the local authority is asked to devise means for establishing contact with the patients. The Ministry anticipates that at first the field of inquiry will be limited to patients seeking treatment at hospitals administered by county and county borough councils and at voluntary hospitals, no difficulty being expected in securing friendly coöperation here. We do not ourselves see how it could be extended further without violating confidence. A questionaire in the appendix indicates the general lines on which inquiry might be made. Particulars about the patient himself, his history before and after coming under the observation of the local authority, and his subsequent history, whether or no radical treatment has been undertaken, should be ascertained. We welcome this official encouragement of geographical research, because it may give enlightening results. At the very least it should show where a further distribution of radium is required and where better provision is needed for the succour of inoperable cases.

ANNOTATIONS

HEART DISEASE AS A SURGICAL RISK.

THE association of heart disease with conditions requiring surgical interference calls for some of the most difficult decisions in medicine. On the basis of 414 cases an attempt has lately been made[1] to assess the risk in different types of cardiac disease. Major and minor operations of all types are included in the series, and the various forms of anæsthesia are not differentiated. The deaths are classified as "unexpected" and "inevitable," the latter including cases in which operation gave the only hope of recovery, although the patient was expected to die from causes other than heart disease. Consideration is chiefly given, of course, to the deaths from unexpected cardiac failure, probably caused by the operation. Among 120 patients who had valvular disease the unexpected mortality was only 2·1 per cent., while among 138 with chronic myocarditis, and 87 with permanent auricular fibrillation, it was only 4·9 and 3 per cent. respectively. An unexpected death occurred in a group of 17 cases of paroxysmal flutter or fibrillation, and one among 11 cases of syphilitic aortitis and incompetence. Twenty cases of coronary thrombosis provided eight unexpected deaths, but in five of them the diagnosis was overlooked before operation, and in seven the attacks followed operation. There were three deaths among 38 patients who had signs of failure before operation, and four among 12 patients who developed failure after operation. Out of 55 with a combination of nephritis and heart disease, eight died unexpectedly, which suggests that this combination adds greatly to the operative risk. A study of the incidence of raised blood pressure showed that it was the nephritis rather than the raised blood pressure which was dangerous, for patients who had a very high blood pressure were mostly good operative risks. An analysis of age incidence shows that the general opinion that the surgical risk becomes greater with advancing age is true for cardiac patients. The gist of the reviewers' conclusions is that in most forms of heart disease the surgical risk is not appreciably increased, but they emphasise the importance of accurate preoperative diagnosis and treatment.

CHARCOT'S ARTHROPATHY.

ELSEWHERE in this issue Dr. Harold Avery reports a case of Charcot's arthropathy affecting a site not hitherto described, the sacro-iliac joint. There is a widespread impression amongst clinicians that the Charcot joint is a somewhat mysterious entity which eludes explanation. It is true that in some ways —in the grotesque disorganisation of the affected joint, for instance—the condition is peculiar. Yet a recent paper by E. J. S. King[2] of Melbourne, suggests that these peculiar joint changes can easily be interpreted in terms of fundamental pathological principles. It is generally agreed that the primary ætiological factor is damage to the sensory nerves supplying the joint and, as the precise level at which the sensory pathway is interrupted is of no consequence, Charcot's disease is found in conditions as widely apart in nature and situation as peripheral neuritis and syringomyelia. Anæsthesia is not, however, the sole factor. Experiments on animals have shown that the anæsthetised joint remains healthy as long as it is protected from injury, but that subsequent trauma produces typical Charcot's disease. R. Leriche made some interesting observations on the fate of fragments of bone implanted into the joints in animals. Dead bone gave rise to no very striking reaction, whereas living implants provoked an extensive reaction in the surrounding tissues, characterised by marked polypoid thickening of the synovial fringes and extensive new formation of cartilaginous and bony tissue. A similar hyperplasia, almost sarcomatous at first sight, is commonly seen in the process of callus formation after fractures, the connective tissue cells having regained their embryonic power of forming cartilage and bone. King has found this same exuberant metaplasia around the joints in Charcot's disease, and in one case an isolated fragment of necrotic bone occupied the distorted joint cavity. From these considerations he is led to suggest that Charcot's disease is merely an exaggerated form of osteo-arthritis in which the stimulus to the inflammatory reaction is supplied by the products of dissolution of small fragments of necrotic bone. The reaction of the tissues is exaggerated simply because the anæsthetic condition of the joint permits frequently recurring trauma, of which the patient is unaware.

A MEDICAL FILM LIBRARY.

Messrs. Kodak have now in London the nucleus of a valuable library of medical films. The potential importance of cinematography in medical education was early appreciated, and a surgical operation was filmed at the West London Hospital as long as 25 years ago. With improvements in apparatus and technique it has now become possible to record a wide variety of subjects. The Kodak library at present contains about 60 films made in this country and abroad. They are classified under various headings—e.g., anatomical, neurological, obstetrical, surgical, physiological, dental, and veterinary—and they will be found increasingly useful by demonstrators and teachers. Some are intended to show to students the detail of accepted technique; others enable practitioners to study the methods of distant clinics. As an example of the first group we may mention a film on blood transfusion which shows the surgical procedure in such detail that several experienced donors collapsed on seeing it. A border-line example is a record of prostatectomy by Sir John Thomson-Walker, which is an undoubted triumph but would probably be of greater use to the well-informed than to the ignorant. For the surgical student the advantage of the cinema is that it is capable of showing every step of a complex operation; he is presented with a full account of the battle rather than occasional glimpses of a stricken field. Since there is no advantage in photographing an actual operation—and many disadvantages—we believe that in this branch the best results will often be got by taking films from models rather than the living subject. As the value of instructional films is appreciated it will become worth while to spend time and money on making explanatory records for students, and to many minds they will

be far more useful than text-book descriptions. The Kodak library already contains diagrammatic films, and they will convince the sceptical. Impressive, but possibly less successful from the learner's standpoint, are the films where natural processes are accelerated. The development of a rabbit ovum at 360 times the normal speed has an air of liveliness which seems scarcely proper even in a rodent.

We hope that medical societies and similar bodies will make abundant use of the library, and notably of the films demonstrating foreign methods—e.g., the management of normal birth in the gynæcological clinic of Berlin University. Special attention may perhaps be drawn to a 52-minute reel which shows the diagnosis and treatment of infections of the hand and has been made under the authoritative direction of Dr. A. B. Kanavel, of Harvard While it appears that Messrs. Kodak are helping to make travel unnecessary, the inclusion of such films will do much to disprove the sublime saying that "to travel is to discover that everybody is wrong."

The catalogue is obtainable from Kodak House, Kingsway, W.C.2.

THE PATHOGENESIS OF ECZEMA.

SINCE the early days of scientific dermatology, research has eliminated from the conditions, formerly grouped loosely together as "eczematous," a host of disorders of the skin, by discovering their true ætiology, and placing their pathogenesis and treatment on a secure foundation. In this category are to be found the skin ailments due to fungi and yeast, seborrhœic dermatitis, trade "eczemas," and those which exhibit a special idiosyncrasy to such a variety of noxæ as primula, turpentine, cat fur, and so forth. After eliminating them we are left with a group in which no demonstrable cause or "antigen" is found to account for the peculiar inflammatory symptoms for which the name of eczema must still serve. Examples of typical reactions were given by Prof. W. Scholtz in a paper communicated to the German Dermatological Congress at Königsberg.[1] For instance, a little iodoform gauze applied to a wounded finger produces on the following day a crop of vesicles at the site of application. The patient has developed iodoform dermatitis, which subsides on withdrawal of the dressing but will recur in loco whenever iodoform is reapplied. The patient is said to have an idiosyncrasy to iodoform, but is not affected by any other irritant such as mustard oil, croton oil, or capsicum. He remains well unless he comes in contact with iodoform. Another patient reacts to iodoform in the same way, but the dermatitis spreads in spite of withdrawal and careful removal of all traces of the iodoform from the area of local contact to the hand, forearm, and other places, and after subsiding may, perhaps, light up again and again either locally or in distant areas. On inquiry one may perhaps elicit the fact that the patient has had previous attacks of a weeping skin eruption, and is sensitive to a number of skin irritants. The diagnosis in this case is iodoform dermatitis in an "eczematous" subject, and the outlook in the two cases is entirely different. In the first we are entitled to assume that the patient will remain well so long as he avoids iodoform, while in the other we can never be sure how long he will remain free from the tiresome symptoms of his eczematous diathesis. The facts are still further complicated by the existence of a third type of reaction. This concerns the individual —usually a workman—whose reactions are strictly localised to the hands, which in the course of years of exposure and traumatism of all kinds eventually become sensitive and react with the production of eczema to even the mildest irritants; or the trouble may arise when the hands are used in any light employment, but remain well if protected in gloves or kept greased with salve. Similar examples of local susceptibility are met with on the face, the scrotum, or on the shins, and in such cases we have to deal not with a sensitiveness to any particular irritant (allergy), but to a presumed anatomical or biochemical alteration of the epidermis of the affected area. In thus subdividing the manifest examples of a complex disease we must not lose sight of the fact that there are individuals who cannot be accurately grouped in any one of the three specified classes. There must always be intermediate and "passage" cases in any system of artificial classification.

The whole question of eczema and its causation is of the greatest interest. Among those who are engaged on its investigation the name of Dr. Bruno Bloch, of Zurich, stands prominent at the present time. He has succeeded in reproducing the complete clinical and histological picture of eczema in guinea-pigs, by introducing by injection (or local application) the ethereal extract of the irritant substance of *Primula obconica*. This is actually the first occasion in which a permanent allergic cutaneous reaction of the skin had been successfully conveyed to animals, and the accomplishment is likely to lead to a material progress in the therapeutics of eczema. The details of his work, which have already become widely known, will form the substance of a paper to be read at the forthcoming International Congress of Dermatology to be held at Copenhagen. Prof. Darier, of Paris, will be the principal speaker, and his address will be followed by that of Prof. Jadassohn, of Breslau, while those taking part include such well-known names as Bloch, Oppenheim, Sabouraud, and Whitfield. After many years in which progress has been slow, it seems that at last this most important problem in dermatology is on the way to solution.

HISTORICAL ADDITIONS TO THE HUNTERIAN MUSEUM.

THE historical series of the Museum of the Royal College of Surgeons of England has been enriched by several gifts. Among these is a mahogany medicine chest that formerly belonged to Dr. Edward Jenner, the discoverer of vaccination, with most of its fittings intact. This beautifully made little cabinet is of the type commonly found in doctors' surgeries about the end of the eighteenth century. The upper part, which has a hinged lid, is fitted with four wide-mouthed bottles with metal caps for holding powders, and in a separate compartment is a pewter medicine measure, a small pewter funnel, and two palette knives with silver handles. Here, also, is a receptacle for the scales and a box with a sliding cover for the weights. In the front compartment, which opens with a door, are five stoppered bottles of four-ounce capacity, and below are seven drawers with ivory knobs. Five of these are divided into four compartments with sliding lids for containing powders, one of which still contains some compound senna powder, a remedy much in vogue in Jenner's time. The two drawers below are each fitted with four glass jars for ointments, and contain the remains of yellow basilicon, zinc and spermaceti ointments. Another compartment, which occupies the back of the cabinet, contains

eight stoppered bottles for liquids, each of eight-ounce capacity. This relic is fully authenticated.

Another interesting gift is a fine compound microscope that belonged to Sir William Bowman, the first President of the Ophthalmological Society of Great Britain, presented by his grandson. It was used by him in making his classical discoveries. It is one of the early massive achromatic instruments of the last century, and was made by Hugh Powell in 1840. A case of ophthalmic instruments used by Sir William has also been presented. An extraordinary ju-ju or fetish that was taken from a notorious witch-doctor at Ohitsba, in Nigeria, which mainly consists of human skulls and bones, has been added to the collection. It is made up of a "mass" of vegetable matter (the witch-doctor's medicine), bound together with fibre and surrounded by a circle of eight human skulls, one of which has an indentation probably caused by a blow. Dr. Aly Bey Ibrahim, of Cairo, has given two old native Egyptian trusses, made and used in that country about the seventeenth century. These primitive appliances are made of hoop-iron, crudely covered and padded with black and white cotton. A palm-leaf manuscript from Ceylon, enclosed in wooden covers, decorated in red and white, is the gift of Dr. Casey Wood. The leaves are inscribed with medical recipes, and notes given by a senior native physician to his pupils, and recorded by the student from time to time.

The collection of amputation saws has been augmented by a specially arranged series showing the development of the instrument from the flint saw used by the ancient Egyptians about 4000 years ago. It includes examples of the early bow-saw employed in the thirteenth century, saws used in the time of Ambroise Paré, and specimens of the tenon-saw of the eighteenth century used by Percival Pott, and also shows the improvements made in the instrument down to the close of the nineteenth century.

THE MENTAL RADIO.[1]

Mr. Upton Sinclair's books have acquired and deserved a large circulation, but he breaks entirely new ground in writing of telepathy. His wife, however, having discovered in girlhood that she possessed some power of mind-reading, the opportunities for an intimate study of telepathy thus offered to Mr. Sinclair have produced in him a complete conviction the spirit of which will be found throughout the book as shown in these words. "For the past three years," he says, "I have been watching this work, day by day and night by night in our home. So at last I can say that I am no longer guessing. Now I really know. I am going to tell you about it, and hope to convince you; but regardless of what anybody can say, there will never again be a doubt about it in my mind. *I know.*" Prof. William McDougall, who provides an introduction to the book, is sympathetic, for he writes: "Mrs. Sinclair would seem to be one of the rare persons who have telepathic power in a marked degree and perhaps other supernormal powers. The experiments in telepathy, as reported in the pages of this book, were so remarkably successful as to rank among the very best hitherto reported. The degree of success and conditions of experiment were such that we can reject them as conclusive evidence of some mode of communication not at present explicable in accepted scientific terms, only by assuming that Mr. and Mrs. Sinclair either are grossly stupid, incompetent, and careless persons, or have deliberately entered upon a conspiracy to deceive the public in a most heartless and reprehensible fashion."

The very first illustration of what Mr. Sinclair calls "a mental radio" does appear to close the usual avenues of doubt. A man "agreed to make a drawing of any object he might select at random and then to sit gazing at it concentrating his entire attention upon it for a period of from 15 to 20 minutes." The obvious ambiguity in the quoted sentence has, it seems, no bearing on what happened. "At the same agreed hour . . . . Mrs. Sinclair was lying . . . . forty miles away . . . . in semi-darkness with her eyes closed, employing a system of mental concentration." As a result she took pencil and paper and wrote, with the date, in six words exactly what the drawing would be found to be. And so it was. The book continues to set out in illustration, successes, partial successes, and failures in a series which are summarised by the author thus: "I have now given nearly all of the 65 drawings which I call 'successes' and about half of the 155 which I call 'partial successes.' This, I think, is enough for any purpose. No one can seriously claim that such a set of coincidences could happen by chance, and so it becomes necessary to investigate other possible explanations." Prof. McDougall's verdict is that Mr. Sinclair's book will amply justify itself if it leads readers to undertake carefully and critically experiments similar to those described.

THE BLOOD-SUPPLY OF THE LIVER.

It would be generally thought that the blood-supply of the liver is pretty well understood, and in a rough way this is no doubt true. But we gather from a paper by Dr. G. R. Cameron and Dr. B. T. Mayes,[1] on the results of tying the hepatic artery, that there is still a good deal to find out and say on the subject. What, for example, is the precise relationship between the portal vein and the hepatic artery? The portal vein can be injected quite easily from the hepatic artery and a radiogram of a liver treated in this way with lipiodal is very similar to one of a liver into which the injection has been put via the portal vein. No arterio-venous anastomoses between the two sets of vessels could be found within the liver. It appears that the hepatic artery after entering the hilum breaks up into capillaries which supply mostly the walls of the portal vein and the bile-ducts. These reunite into venules which join the venules of the portal vein either in the portal canals or at the periphery of the liver lobules, and it is this conjoint stream which passes into the sinusoids and supplies the parenchyma. There seems to be no justification for the idea originating and being mostly propagated in pathological circles, that the hepatic artery specially supplies the outer zone of the liver lobule; all parts of the lobule receive the same blood, which varies only in so far as it becomes deoxygenated on its passage towards the intralobular radicle of the hepatic vein. Cameron and Mayes suggest that the hepatic artery does not differ in its general plan from the mesenteric arteries.

It is also clear from the observations and experiments now recorded that the liver receives more than negligible quantities of blood from sources other than the hepatic artery and portal vein. Deprivation of any part of the liver of portal blood leads to a slow disuse-atrophy of the corresponding liver cells; deprivation of arterial blood results in

[1] Jour. Path. and Bact., 1930, xxxiii., 799.

acute necrosis and degeneration. Though ligature of the whole of the hepatic artery leads to necrosis of so much liver that the animal usually dies, yet the necrosis by no means involves the whole liver. The experiments on tying the various branches of the hepatic artery must be considered in relation to the anatomy of the rabbit, which was the animal they used, but it is surprising how much of the artery, especially in young animals, may be made functionless without causing any necrosis at all. Cameron and Mayes found too that, if the whole of the hepatic artery, portal vein, bile-duct, and inferior vena cava above and below the diaphragm were tied, methylene-blue injected into the jugular vein could be seen to enter the liver almost at once. There are no named arteries which could account for this, but it is evident that there is an abundant collateral supply through the diagphragm and from the abdominal connective tissue which is of considerable importance in maintaining the vitality of the liver cells. In a full and scholarly discussion of the literature the authors point out that the results of accidental ligature of the hepatic artery and parts of it in man vary from death to no symptoms, and their results explain the apparent immunity in which some surgeons have been able to rejoice.

PUBLIC HEALTH SERVICES AND THE MINISTRY OF HEALTH.

SOME changes are notified in a circular (No. 1129) addressed to local authorities by the Ministry of Health in the annual returns required by the Minister in connexion with the maternity and child welfare, tuberculosis, and venereal diseases services.

The following returns will be dispensed with: (1) annual returns giving detailed statistics of the work of homes and hospitals for mothers and for children; (2) annual returns giving summary information as to the work performed at treatment centres for venereal diseases, and as to the treatment of these diseases in poor-law institutions and in hostels; (3) monthly returns giving the numbers of patients in residential institutions approved for the treatment of tuberculosis, and the numbers of empty beds, on the first day of each month. On the other hand, returns not previously supplied and now required include :—

Maternity and Child Welfare.—Annual returns relating to any maternity home or hospital provided or subsidised by the local authority, and to the maternity wards in institutions newly transferred to them. Moreover, since the previous Exchequer grants to voluntary associations have been replaced by annual contributions from the appropriate local authorities, the returns furnished by local authorities must include the maternity and child welfare work of these associations.

Venereal Diseases.—An annual return (*a*) from medical officers of treatment centres, and (*b*) from pathological laboratories which are approved under the Public Health (Venereal Diseases) Regulations, 1916.

Tuberculosis.—Annual returns of notifications, and of cases remaining on the registers of notifications at the end of each year.

The Minister has also decided to require an annual return showing (*a*) the amount and nature of the accommodation available for the treatment of the sick in institutions transferred to the councils and in general hospitals provided under the Public Health Acts or the Local Government Acts; and (*b*) the use made of the accommodation during the year.

ALLVAR GULLSTRAND.

THE death is announced of Prof. Allvar Gullstrand at the age of 68. He was appointed professor of ophthalmology in the University of Stockholm in 1894, and subsequently professor of physiological and physical optics. In 1911 he received the Nobel Prize for his researches in the dioptrics of the eye, and in the same year he demonstrated the first model of the slit-lamp with which his name will always be associated. This is the instrument by means of which, in conjunction with the corneal microscope, it is possible to examine an anteroposterior section of the anterior part of the living eye, and its use has given us much new knowledge of the structure of the cornea and of the crystalline lens, both in normal and in diseased conditions. Prof. Gullstrand was an honorary member of the Ophthalmological Society of the United Kingdom.

Sir Charles Sherrington, O.M., Waynflete Professor of Physiology in the University of Oxford, and Dr. J. A. Arkwright, F.R.S., honorary bacteriologist to the Lister Institute of Preventive Medicine, have been appointed members of the Medical Research Council in succession to Sir Frederick Hopkins and Sir Charles Martin, who retire on Sept. 30th.

INDEX TO "THE LANCET," VOL. I., 1930.

THE Index and Title-page to Vol. I., 1930, which was completed with the issue of June 28th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

ROYAL MEDICAL BENEVOLENT FUND.—At a recent meeting of the committee 34 grants were made amounting to £515. The following are particulars of some of them :—

M.R.C.S., aged 80, with wife aged 70. Has been in practice for over 50 years, but latterly, owing to increasing deafness, there was a falling off of patients and corresponding loss of income. The daughter, aged 40, looks after her aged parents. The three live on a total income of £184 a year. £150 of this is contributed by a son, aged 39, who is a bank cashier at a salary of £425, and has to keep himself in lodgings. Voted £40.

Widow, aged 51, of L.S.A. who died in July, 1930, aged 71, and who was helped by the fund during the last two years of his life. He was also in receipt of an allowance of £104 a year from another charity, as he was unfit for work and in receipt of the old age pension. The widow has been left with nothing. The allowance of £104 has been discontinued as the widow is not eligible for this help, and the old age pension has been stopped. The widow has obtained a post as companion to an old lady at a salary of £1 a week, without food. Owing to a recent accident and a broken wrist active employment with larger salary is difficult to find. Voted £26.

Widow, aged 63, of M.D. Husband died in 1929, leaving his widow destitute, her only support being her daughter, who is earning 48*s.* a week. Voted £26. Epsom College has also given a pension.

Widow, aged 55, of M.B. Husband suffered from tuberculosis since 1897, and died in 1919. His money was mostly invested in Germany and has been lost. The widow supported herself by taking in paying guests, but owing to diabetes has been unable to do much work. She has been further handicapped by her son, aged 30, who has congenital heart trouble. The presence of the son in the house has frightened away guests who otherwise would have stopped. Voted £26.

Subscriptions and donations are urgently needed in order that the activities of the fund may be continued and applicants given the help they need. Cheques should be forwarded to the honorary treasurer of the Fund at 11, Chandos-street, W. 1.

MODERN TECHNIQUE IN TREATMENT

A Series of Special Articles, contributed by invitation.

CCCIV.

THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS.

PART II.*

Phrenic Evulsion.

EITHER dome of the diaphragm receives its nerve-supply through the phrenic nerve. Destruction of this nerve-supply causes paralysis of the dome and atrophy of the muscle-fibres. As a result of this the dome rises up into the thorax, partially on account of the intrathoracic negative pressure, but mainly because of the intra-abdominal pressure. The maximum rise is not seen until complete atrophy of the muscle has occurred. During respiration paradoxical movements may be seen, the paralysed dome rising with inspiration and falling with expiration. The extent of the rise varies greatly in different individuals, depending on the extensiveness and character of the basal adhesions. It may be as little as 1 or 2 cm. or as much as 7 to 8 cm. The effect of these changes in the dome of the diaphragm is to diminish the size of that half of the chest and so to allow of a measure of collapse of the lung; also to relax all tension from the structures in immediate direct or indirect contact with the upper surface of the dome. The reduction in the size of the hemithorax results in a partial collapse of the lung. In some cases this collapse is mainly confined to the base, but in others it affects the whole lung to such an extent even that cavities in the apex become considerably reduced in size. The abolition of the tonic contraction of the muscle and the relaxation of the strain on adjacent structures abolishes such symptoms as the constant, reiterated, purposeless cough so characteristic of diaphragmatic irritation; it removes the dragging ache and pain associated with basal adhesions; it restores in part the heart and mediastinum displaced by chronic fibroid contraction, and diminishes the tachycardia and dyspnœa which may be an accompaniment of this change.

The realisation of these changes enables one to appreciate how great is the field of usefulness of hemidiaphragmatic paralysis. There is, however, a limitation of this field due to the uncertainty of the amount of rise of the dome. Fortunately the operation is of such comparative simplicity that the risk of this uncertainty is worth taking.

The indications for hemidiaphragmatic paralysis by phrenic evulsion, briefly stated, are :—

(1) For cases of basal tuberculosis. It may also be helpful in basal bronchiectasis, but more often than not the results are disappointing.

(2) For cases of more extended tuberculosis which require additional treatment to arrest the disease. As already pointed out, even cavities in the upper lobe may have their walls approximated as a result of the rise of the dome following evulsion of the phrenic.

(3) As an accessory to artificial pneumothorax : (*a*) when the base is held out by adhesions; (*b*) to lengthen the interval between refills; (*c*) it is said to check the occurrence or recurrence of pleural adhesions; (*d*) to reduce the size of the hemithorax when the collapse is being given up and the lung being allowed to re-expand.

(4) For the treatment of symptoms such as cough, tachycardia, and dyspnœa.

(5) As a preliminary to thoracoplasty.

* Part I. appeared last week.

The original operation of simple section of the phrenic nerve was often a failure. The reason of this is that the nerve originating from the fourth cervical and possibly from the third and fifth cervical roots also, and crossing the scalenus anticus muscle, is not always the sole source of supply. There is frequently an accessory phrenic nerve arising from the brachial plexus, sometimes from the nerve to the subclavius muscle, and not infrequently jointly with the suprascapular nerves. This accessory nerve passes downwards and joins the true phrenic in some part of its intrathoracic course, usually about the level of the first rib.

The destruction of this possible dual source of supply is accomplished by evulsion of the phrenic nerve. The operation is a comparatively simple one, done under local analgesia. The phrenic nerve is reached in the neck through an incision 2 to 2·5 cm. long, made at the outer border of the sternomastoid muscle at about the level of the cricoid cartilage. The phrenic nerve is exposed as it crosses the scalenus anticus muscle; it is divided, and then the distal end is drawn out of the wound. In a successful case of evulsion the whole nerve, including the terminal filaments detached from the diaphragm, will be withdrawn. Often the nerve breaks; but if some 10 to 12 cm. of nerve have been evulsed, hemidiaphragmatic paralysis will have been achieved.

EXTRAPLEURAL PNEUMOLYSIS.

Extrapleural pneumolysis is an operation most often done over the apex of the lung, and is then called apicolysis. A localised collapse of the lung, together with the parietal pleura, is produced by stripping this membrane away from the deep surface of the chest wall. The lung in part retracts and in part is displaced by the operator, and a space is left between the outer surface of the parietal pleura and the chest wall. As the air in the space would soon be absorbed with consequent re-expansion of the lung, it is necessary to fill the cavity with some substance which will maintain the lung collapse. Paraffin, with a melting-point of 110° or 112° F., is one of the substances so used. It has, however, the disadvantage that it may irritate the pleura and cause an extrapleural effusion, the fluid from which opens up a track through the wound and, escaping, carries with it the paraffin. Transplanted fat may be efficacious; on the other hand, it may liquefy and, working its way to the surface, eventually discharge through the skin. Some surgeons use a packing of gauze or of rubber strips which are later removed. The cavity is then allowed to become obliterated by granulation tissue. My own preference is for a living, pedunculated graft, using the pectoral muscles in men and the breast in women.

The indications for the operation are localised lesions with or without cavities, especially those situate in the apex of the lung. It is also used after thoracoplasty to supplement the collapse obtained by this operation when there is a thick-walled cavity which has resisted collapse. The operation is not one particularly gratifying in its results, for which reason it is not often done. There are, however, certain cases for which a localised apical collapse is particularly indicated. For such cases I have recently been trying a localised modification of the extrapleural thoracoplasty. The rib resection in these cases is localised to the first four or five ribs up to the transverse

rocesses, but the total length of bone resected is onsiderably more than would be done if one was iming at collapse of the whole chest wall. For instance he length of bone removed from the first rib is from ·5 to 4 cm., and of the fourth rib 12·5 cm. or more. his operation of localised thoracoplasty causes no ore shock and does not take as long as apicolysis. he risks of tearing the lung are less, as also are the isks of post-operative complications. So far as my xperience goes the results are most gratifying and ore constant.

Thoracoplasty.

The object of the operation of extrapleural para-ertebral thoracoplasty is to obtain collapse of the ung by mobilising the ribs so that they fall in towards he spine and mediastinum, and so greatly diminish he corresponding side of the chest. This is achieved y resecting lengths varying from 2·5 cm. to 12 or 5 cm. from the posterior ends of the ribs right up o the transverse processes. The operation is usually lone under a combination of local and regional næsthesia and of a general anæsthetic. When the lisease is extensive the resection must be of the first 0 or 11 ribs, and is then done in one or two stages ccording to the general condition of the patient, the tate of cardiac sufficiency, and the amount of putum. For disease confined to the upper part of he lung, resection of the first seven or eight ribs in ne stage will suffice. Always, however, the first rib ust be included, since each rib is slung on to the one bove, and so on up to the first.

This operation is indicated in those cases which are ot responding to sanatorium treatment, or in which æmorrhage is a serious or recurring symptom and n which an artificial pneumothorax has failed. In ng-standing cases of intense fibrosis with multiple avitation and sacculation of the bronchi, thoraco-lasty is preferable to artificial pneumothorax. The ontra-indications are much stricter than for pneumo-horax. It is essential that there is no activity of the lisease in the opposite lung. Sometimes it is very lifficult to distinguish between persistent catarrhal moist sounds at the apex of a lung and the crepitations of activity. Observation of these sounds over a long period alone can help to differentiate between them. The mortality as a result of the operation is about 5 per cent. The results of successful intervention are, nowever, most gratifying as the collapse is permanent nd not a continually varying one, as in artificial neumothorax. The late results collected by J. Alexander show that 36·8 per cent. are healed and 24·4 per cent. benefit by the operation. Despite the collapse of the chest wall, the resulting deformity is extremely small and not noticeable when the patient s clothed. There should be no interference with the ree movement of the arm. The patient, moreover, s even less handicapped than with an artificial neumothorax, as there is no question of recurring ttendance for treatment by refills nor the risk of leural complications.

Multiple Neurectomy.

The excision of parts of each of the intercostal nerves leads to a paralysis of the intercostal muscles. The effect of this, especially when combined with phrenic evulsion, is to immobilise the corresponding side of the chest wall and to cause slight falling in of the chest wall. The operation has been suggested by Alexander for cases needing a thoracoplastic operation, but in whom there is contra-indication owing to the extensiveness of the disease or the frailty of the patient.

Conclusion.

These operative procedures and the results obtained by them show that surgery has immense value in the treatment of pulmonary tuberculosis. They show also how indispensable surgery has become in supplementing sanatorium treatment, and how essential it is, therefore, that surgical facilities should be regarded as a necessary part of the equipment of every sanatorium.

H. Morriston Davies, M.D., M.Chir. Camb., F.R.C.S. Eng.,
Medical Superintendent, Vale of Clwyd Sanatorium; Consulting Surgeon, University College Hospital.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdrs. A. W. Cocking and W. E. Heath to be Surg. Comdrs.

Surg. Comdr. G. E. D. Ellis is appointed to the battleship *Iron Duke*, and Surg. Comdr. R. N. W. W. Biddulph to the *Victory* for duty in Portland Dockyard.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. (D) G. K. MacLellan to be Surg. Lt.-Comdr. (D).

Surg. Sub.-Lts. A. Elliott, W. J. Poole, and V. S. Hughes-Davies to be Surg.-Lts.

Prob. Surg. C. Mason to be Surg. Lt.

The following appointments are notified: Prob. Surg. Lt. W. H. Roberts to *Marlborough*, for training; Prob. Surg. Sub-Lt. P. B. Moroney to *Norfolk*, for training.

ROYAL ARMY MEDICAL CORPS.

Lt. F. M. Collins to be Capt.

ROYAL AIR FORCE.

Flight-Lt. H. O. Sumerling is promoted to the rank of Squadron Leader (Dental) on promotion to Major in the Army Dental Corps.

INDIAN MEDICAL SERVICE.

Col. C. A. Sprawson to be Maj.-Gen.

Lt.-Col. J. C. S. Oxley retires.

The probationary appts. of the under-mentioned officers are confirmed: To be Lts.: K. F. Alford (now prov. Capt.), H. S. Waters, J. H. Boultbee, H. T. McWilliams, P. Shannon, H. J. Curran, E. A. Y. Mackeown, W. P. Lappin, B. J. Griffiths, G. Milne, A. M. Fraser, D. L. Trant, A. M. Sheridan, and P. J. Walshe.

Dewan Pitamber Nath to be Lt. (T.C.).

Rheumatic Clinic for Brighton.—The Health Committee of Brighton Corporation has approved a scheme for building a new rheumatic clinic at a cost of £75,000. The local branch of the British Medical Association has given its support and, on the recommendation of Dr. Duncan Forbes, the medical officer of health, the Silwood Hall Hotel is to be bought for the purpose for £25,000; the cost of remodelling the building will be a further £35,000. It is estimated that the clinic will allow of 85,000 treatments a year, and that the income would be about £17,000.

Coördination of Liverpool Municipal Hospitals.—Reporting to the Liverpool public assistance committee, the medical officer of health, Dr. A. A. Mussen, propose that the whole of the municipal hospital service should be brought under the management of the port sanitary hospitals committee, and advises the erection of a new hospital in the outskirts, on a site sufficiently large to provide for extensions. In the ten poor-law institutions now managed by the public assistance committee there are 9813 beds, as compared with 1635 beds in the eight hospitals, and about 300 children's cots, administered by the port sanitary hospitals committee. By a large majority the public assistance committee has approved the principle of the report which is to be sent to the Liverpool voluntary hospitals representative committee for consideration.

SPECIAL ARTICLES

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING IN LONDON.

PROCEEDINGS OF THE REPRESENTATIVE BODY.

(*Concluded from p. 209.*)

Dr. H. B. BRACKENBURY put four points before the meeting, having reference to conditions under the new Local Government Act.

Effects of Local Government Act.

First, he asked, what could the local authorities do to further the Association's policy of unification of health services? On April 1st the vaccination and infant life protection services had been handed over by the poor-law authorities to the care of the public health authorities. Certain services had received permission from the new authorities for administration under other Acts than the poor-law; for example, some pauper children would be dealt with under the Education Act, and others, who were blind, under the Blind Persons Act. The new authorities were also at liberty to appropriate poor-law institutions for public health purposes. In addition, every local authority had appointed a public assistance committee, and could delegate to this committee its poor-law functions, both advisory and executive. The public health committee might in turn delegate part of its work to other committees; pauper mentally deficient children, for example, could be handed over to the committee for mental deficients. Dr. Brackenbury next spoke of the position of district medical officers. It was proposed that the Association should ask that whole-time officers, apart from exceptional circumstances, should not be engaged in domiciliary attendance on the indigent poor. These patients, it was felt, should come under the care of general practitioners, or part-time officers, for two reasons: in order that the patient might have the advantage of a free choice of practitioner, and so that no one need be under the stigma of "having to have the poor-law doctor."

The third subject raised was representation on local authorities. The law prohibited any person in the employment of a local authority from being a member of that authority. The result of this was that it was gradually becoming more and more difficult for any member of the medical profession to be engaged in public work, and this was not an advantage from the point of view of the community. Some arrangement should be sought with the Ministry of Health to effect a change in the law.

The speaker's fourth point concerned the superannuation of those poor-law medical officers who left their posts on April 1st. Up till that time many of them had been members of their local authorities, but under the new Act they were forced to resign either their membership or their office. Those who had chosen to continue their public work, and to leave their medical post, lost all their savings under the superannuation scheme to which they had been contributing compulsorily for years. Yet, had they been dismissed for misconduct, their money would have been refunded to them. The numbers who had suffered in this way were few, but the injustice was a striking one. The Association had succeeded in placing a one-clause Bill before Parliament, but it had not been pushed. It was desirable that public opinion should be brought to bear to get the Bill passed.

Dr. H. KERR expressed the thanks of whole-time medical officers to the Association for opposing the first draft of the poor-law order. Under this draft the medical profession had been subordinate to the public assistance officer. The recall of this clause, and substitution of less objectionable terms had been due to the Association.

Medical Patents.

In the absence of Dr. ARNOLD LYNDON, Dr R. LANGDON-DOWN introduced the subject of patents, his motion being that it was ethically undesirable for a registered medical practitioner to derive financial benefit from the sale of the rights or from royalties for any invention or discovery in the medical field which he might make. The Council had been approached by two outside bodies for a ruling on this point. One of these, an industrial body, the Association of British Chemical Manufacturers, was anxious to know whether the attitude of the medical profession had changed; it had always been taken for granted that medical practitioners were opposed to any monopoly implied in patenting. In 1927 an opportunity had occurred for testing this attitude when insulin was patented and handed over to the control of the Medical Research Council. The profession had always used strong expressions against private patenting in the past, and would doubtless still object to monopoly, secrecy, and hindrance to research. On the other hand, practitioners would be equally anxious to be free of any charge of hindrance to industry or commercial research. It would probably be possible to dedicate a patent compulsorily to a public patents trustee. Practitioners might consider that the time had come to sweep away all restrictions on private patenting, but if it was felt to be undesirable to abolish this 300 year-old principle an amendment on the lines indicated might be considered. This was a matter for the profession as a whole; the General Medical Council was concerned with medical education, the maintenance of the Register, and the indication of the low line of medical conduct.

Patenting tended to produce secrecy in the worker, it did not encourage the early publication of results and it fostered haste and rivalry of an undesirable kind, rather than the scientific detachment required for research. Moreover, it gave the great reward to the man who laid the last brick on an edifice which might be the work of many. Though intended to safeguard the public from the dangers of monopoly the approach for the removal of an abused patent could not be made for three years. It was unlikely that anyone would wish to patent a discovery of a clinical nature, but a person working in the chemical or biological world could scarcely occupy the clinical field as well, and his discoveries would verge on the commercial. There was now an opportunity for relaxation and adjustment so as to give some freedom of patenting and to safeguard against undue monopoly.

Dr. E. GRAHAM LITTLE proposed that the motion should be referred back to the Council for further consideration. The Council appeared to agree that some form of patenting must be considered, and to be inquiring, merely, into the best way to do it. The

Association could not direct the attitude of the profession, but could only lay down rules for members. In answer to a private inquirer, the President of the General Medical Council had expressed the view that a discovery or invention should be made available for the public good, and that the name of the discoverer or inventor should not be associated with it in order to acquire patients. But it seemed unfortunate to make a separation between the medical profession and other men, and to rob the doctor of a right which any other member of the community was in a position to demand.

Mr. H. S. SOUTTAR seconded the proposal to refer the matter back to the Council. A new situation had arisen, he said, requiring consideration. There was no question but that patents must be taken out; the question was who should take them out. At present patents could be taken out in Germany for chemical preparations invented in England, with the result that English manufacturers could not use them. The chief value of patents would be to protect this country against a foreign monopoly. A patent did not mean secrecy; indeed the condition on which it was granted was that the inventor should publish the method of production in detail. It was, in fact, a guarantee against monopoly, secrecy, and hindrance, to research. He had himself never taken out patents for the plain reason that there was nothing to be gained by it as far as he was concerned. But he had consulted two medical men of first-class ability, researchers on certain organic chemical compounds. One had produced hundreds of preparations for the treatment of a tropical disease; but without the opportunity to patent them he gained no financial recompense for his labours. In these circumstances it was impossible to find a manufacturer to take up the production of preparations which might become the monopoly of foreign firms. This type of work deserved recompense—it required a very high standard of ability. He dissociated himself from the idea that these men should not engage in clinical work for contact between clinical and laboratory work should be encouraged, nor should the profession disparage the man who tried to make a living from laboratory work. Dedicated patents had been suggested to solve this problem; these were excellent from the point of view of the manufacturer, but less satisfactory to the medical man, who would receive back what the public trustee thought fit—a doubtful privilege. As an example of the possible results he cited the case of the inventor of the trench mortar during the late war, who spent £14,000 on its production; this sum he recovered from the nation after much litigation, but 18 per cent. of it was immediately reclaimed in income-tax. He ended with a loss of several thousands of pounds. The point was of great importance to the individual medical man, and should be referred back to the Council.

Dr. F. TEMPLE GREY suggested that as there had been an unwritten law on this point for 300 years it might as well remain unwritten. Why should not the matter of patents be left to each man's judgment and taste? Many of the points put forward against patents were covered by Act of Parliament; it was required that preparations should be put on the market at the lowest possible price, and that the inventor should receive due reward. There was nothing disgraceful in a patent, and no one ought to be removed from the Register for taking one out. The term had been confused by the issue of so-called "patent medicines," which, in fact, were never patented, and of which the composition was kept a secret. The proposal to refer the matter back to Council received further support from Dr. NOEL WATERFIELD, and this course was approved by the meeting. A further motion to refer back to the Council a section on dedicated patents was also carried.

Fees for Midwifery.

Dr. J. W. BONE introduced the Council's proposals for changes in the existing scale of fees paid by local supervising authorities in cases where medical practitioners are called in on the advice of midwives. The present scale, he said, came into force on Jan. 1st, 1923; all the fees were inadequate, but in the past he had been unable to persuade the Representative Body to do more than say so. The departmental committee had now thought it time to revise the fees, and the Council had asked for certain alterations. These were: that the fee of the doctor for attending parturition should be raised from £2 2*s.* to £3 3*s.*; that the fee for attendance of mother and child at the doctor's surgery should be raised from 2*s.* 6*d.* to 3*s.* 6*d.*; that there should be no payment of a fee for services performed by the doctor after the tenth day from his first visit unless he had reported to the local authority that he considered, for reasons stated, that further attendance was necessary, or unless he was called in by the midwife under her statutory rule; and, finally, that the provisions for payment of a fee for visits to the mother other than attendance at labour or miscarriage, for mileage, and for attendance of the mother at the surgery, should also cover ante-natal examinations. The Council had asked for as much as was deemed advisable, and it would be unwise to go beyond a scale which the Association might reasonably expect to obtain.

In the discussion which followed the inadequacy of the old, and even of the revised scale, was stressed.

Dr. H. W. POOLER, speaking of post-partum hæmorrhage, said that no doubt the local authorities could find practitioners to attend cases for a guinea, but that no doctor went to such a case because of the fee. The reasons for his attendance could not be assessed in money. A differentiation between the fee for adherent and the fee for retained placenta had been discussed in his division, but it was felt that it was not easy to draw a dividing line which would satisfy public opinion.—Dr. BONE, in answering the second point, said if the onus of the decision were thrown on the practitioner, the adherent placenta rate would go up.

Amendments to the scale of fees followed each other with such rapidity that they had almost the air of being auctioned from the chair.—An amendment proposed by Dr. C. H. PANTING for South-West Essex finally carried the day in a slightly modified form, as follows:—

> Fee for removal of adherent placenta involving exploration of the uterus, including all subsequent necessary visits during the first ten days, inclusive of the day of birth, £2 2*s.*
>
> This fee not to be payable when the fee of £3 3*s.*, for attendance at parturition and subsequent visits during the first ten days, is payable.
>
> Fee for suturing the perineum, for the treatment of post-partum hæmorrhage, for removal of retained placenta, or for any other operative procedure arising directly from parturition, including all subsequent necessary visits during the first ten days, inclusive of the day of birth, £1 1*s.*
>
> This fee not to be payable when either the £2 2*s.* fee or the £3 3*s.* fee already mentioned in the amendment were payable.

Another proposal was made by Dr. A. S. WILSON (for Holland, Lincs.) providing that the fee for attendance at or in connexion with an abortion or

miscarriage, including all subsequent visits during the ten days from and including the first visit, should be raised from £1 1s. to £2 2s., and this was also carried.

The other suggestions put forward by the Council were allowed to stand.

Birth Control.

A motion was introduced by Dr. BONE, that in the opinion of the Representative Body, where advice on birth control was given at any maternity and child welfare centre (voluntary or municipal) it should be given on medical grounds only, and at the discretion of the medical officer in connexion with any individual case, and not merely because it was asked for by the patient.—This met with disapprobation from Dr. LANGDON-DOWN, who thought it a gratuitous and pernicious invasion of medical liberty. The phrasing, moreover, was ambiguous; what was the meaning of "medical grounds," and did "advice" mean advice on principle or method? The doctor should have absolute liberty to dissuade the patient, or to urge birth control, and to suggest the method he thought best when necessary.—Dr. FOTHERGILL said that in Hove the Labour Party had been trying to establish that every woman who desired knowledge of contraception should have right to attend maternity centres; this would include single women. He agreed that the patient should not determine whether she was to receive information. It was not fitting that anyone should have the right to dictate to members of the medical profession what advice they should give to their patients.

Dr. G. JONES (Lewisham) considered that the unmarried woman had every right to receive information if she desired it. To withhold information would not make her chaste, and if she was determined to practise contraception she should be taught the best and safest methods. The alternatives to contraception were the infinitely greater evils of child murder and abortion. An altered form of the amendment, proposed by Dr. LANGDON-DOWN, was finally carried, and ran as follows:—

> In the opinion of the Representative Body the medical officer at any maternity and child welfare centre (voluntary or municipal) equally with any other medical practitioner, has the right to advise either for or against contraception by methods in accord with his individual judgment and responsibility, and should not be subject to dictation from the patient or her employer in this matter.

Anæsthetics in Midwifery.

Dr. J. YOUNG, speaking of the report of a committee on anæsthetics in midwifery, said that the danger in anæsthesia was due to the toxic effects of prolonged administration. There had been much propaganda in the press during the past year to make anæsthesia available for every woman. There was undoubtedly a risk that if this were made a right, women would be tempted to call for it at an unsuitable stage in labour and the dangers of childbirth would be increased. He asked that the following statement should be incorporated in the report: "In this connexion it is important to emphasise the fact that, unless widely guarded, efforts to extend the employment of general anæsthesia in labour may, by increasing the risk of instrumental delivery at too early a stage, tend to increase maternal mortality and morbidity."

Dr. CHRISTINE MURRELL said that the committee had covered the point freely in the following paragraph of the report: "The common form of anæsthetic used in midwifery in this country is chloroform, or a mixture containing chloroform. Chloroform given during labour diminishes the strength and frequency of the uterine contractions, and the semi-voluntary bearing-down efforts of the mother; it therefore prolongs the labour and increases the use of forceps with the risks that this entails."

Though Dr. YOUNG considered this paragraph to be inadequate, the meeting felt that it should not be asked to incorporate a fresh opinion without more consideration, and passed to the next business.

Ophthalmic Benefit.

Mr. BISHOP HARMAN described the work of the National Ophthalmic Treatment Board, which has now been in operation for a little over a year. The Board is a limited company, and composed of four members appointed from the British Medical Association, and four members of the Association of Dispensing Opticians. The members from each of the bodies have an equal voice on the Board, except on medical matters which are the concern of the medical members only. All expenses for the first year were borne by the Opticians' Association, but at the end of that time it was decided that the British Medical Association should give an equal guarantee, and for this purpose the sum of £1000 was voted. The scheme, Mr. Bishop Harman said, was now in vigorous working order. During the first three months of this year more cases had been treated than in the whole of last year, and during the fourth month the number treated had exceeded all those in the first three months. The value of the scheme lay in the opportunity it gave for the doctor to insist on the examination of his patient by an ophthalmologist. It was important that the profession should have information on the scheme, and its regulations put before it at once.

Dr. D. F. TODD proposed an amendment, for Sunderland, that the action of the Council in voting the sum of £1000 to a commercial optical company be disapproved. He thought the Association was creating a precedent of a serious nature if it stepped into business concerns. The result would be that opticians would again begin to treat without reference to an ophthalmic surgeon.

Dr. HELEN LUKIS opposed Dr. Todd; she thought that time was wasted and much harm done by the optician, who would provide a patient with glasses when the eye condition was referable to a generalised disease like nephritis. The eye was not in a water-tight compartment, and could not be treated without a knowledge of medicine, anatomy, physiology, and pathology. Her only complaint against the new Board was that it was insufficiently advertised.

Dr. PETER MACDONALD pointed out the inaccuracies in the Sunderland amendment. The National Ophthalmic Treatment Board was not an optical company, and the Council had not voted a sum, but had put up a guarantee.—Dr. POOLER was anxious to know how soon the scheme would apply in a practical manner to the rural areas.—Mr. BISHOP HARMAN replied that the Council would consider sending a circular to members of the Association.—Dr. TODD'S amendment was lost.

Lunacy and Mental Disorder.

In moving the annual report under "Lunacy and Mental Disorder," Dr. LANGDON-DOWN mentioned that the Mental Treatment Bill had largely followed the recommendations of the Association to the Royal Commission, and on one point—that relating to non-volitional patients—had adopted the advice of the Association in preference to that of the Commission. The Government had been urged to give the doctor signing documents the status of a witness, but the inclusion of this had not been granted. An

important change of onus had been introduced into the protection clause that no civil or criminal proceedings could be brought against a practitioner without the consent of the High Court, and that this should not be granted unless there was substantial reason to think he had acted in bad faith or without reasonable care.

Dr. D. ROXBURGH said that the Council had failed to obtain that immunity for the doctor which the Representative Body had laid down as a minimum. The profession believed that no doctor would sign a certificate without just cause, and it was no longer necessary to protect the lunatic from cruelty by law. The serious responsibility of giving certificates for lunacy was thrown on those members of the profession who probably had least knowledge of nervous diseases —the general practitioners. It should be laid on those who had the greatest knowledge of the subject. The protective clause was insufficient; how could a high court judge form an opinion without holding an inquiry?—Dr. LANGDON-DOWN demurred; if Dr. Roxburgh wanted the medical profession to be entirely free from risks, he wanted a world at present unattainable. The committee had been chiefly concerned for the welfare of lunatics, whose position was materially improved under the Bill. The report was adopted.

Vaccination.

Dr. E. LEWYS-LLOYD, in moving the adoption of the Public Health Report, asked that the paragraphs on vaccination should be left unaltered.—An amendment, however, was introduced by Sir ROBERT BOLAM, for Newcastle-on-Tyne, suggesting that Government lymph should be made available for general practitioners, and that every practitioner should receive the same remuneration from the Government as the public vaccinator.

Dr. H. KERR removed some misconceptions manifest in this amendment. It had been stated on a previous occasion that Government lymph was the most reliable variety, on the basis of the experience of public vaccinators. But it must be remembered that public vaccinators dealt almost entirely with infants, the reaction of whose skin was slighter. Hence the small incidence of "bad arms." Other producers of lymph had been compelled by the Government to standardise their products, and it was not likely that after enforcing this order the Government would be ready to step into the market as competitors of these manufacturers. Besides, if the Government lymph were made public how could the Ministry of Health control results or collect statistics? Communisation of Government lymph would, in any case, require special legislation. The amendment was also opposed by Dr. Temple Grey and by Dr. Lewys-Lloyd, who pointed out that the wording was not clear. The Government remuneration for vaccination was 1*s.*; it was the local authorities who paid a higher fee. The Newcastle proposal was not accepted by the meeting.

Motor Drivers.

Dr. R. G. GORDON said that the committee on tests for motor drivers was fortunate in having Prof. Joseph Barcroft, of Cambridge, as chairman. The Traffic Bill had now been passed and would probably reach the statute book at the end of the session. This provided for a declaration of fitness on application for a licence, and certain disorders had been made either conditional or absolute bars to driving. The age-limit for motor-cycle riding was to be raised from 14 to 16 years, and for driving public vehicles to 21. No public vehicle was to be driven for more than 11 hours in the 24, or for more than five and a half hours at a stretch.

Dr. C. E. DOUGLAS (Fife) said that the problem had been before the law courts for many years of deciding at what point the driver who had taken alcohol was safe, and at what point he became a danger. A definition of drunkenness published several years ago read to the effect that a man was drunk when he had lost control of his actions to such an extent as to be prevented from being able to execute carefully the work on which he was engaged. But it must be agreed that the point at which he became a danger was the point when he took alcohol into his system. From the beginning alcohol had a sedative effect on some of the higher centres, and work deteriorated in spite of the fact that the subject thought he was doing better. This was a point in preventive rather than forensic medicine. There were times when we were better without alcohol, and one of them was before driving a car. The meeting was unwilling to give a ruling on the subject, and proceeded to the next business.

Public Medical Services.

Dr. H. M. STRATFORD described the poor area of Kensington in which the London Public Medical Service was active. The younger doctors had considerable interest in the scheme, and found it satisfactory and useful. They were not in any sense antagonistic to the Association's scheme, but wished to propose that until that scheme was in working order the Association should support and encourage the London Public Medical Service.—Dr. BRACKENBURY said that the original scheme of this kind which had been put into practice had been initiated and supported by the Association. To encourage such schemes had always been the accepted policy.

Dr. FOTHERGILL said that since the beginning of the century the State had been initiating health services, which were now encroaching on private practice. An effective general medical service had been outlined in the proposals of the Council, but to bring the scheme into action the local authorities and voluntary bodies must share the principles involved. He therefore introduced a motion to suggest that the Council should make every endeavour to secure the acceptance by the central and local health authorities, voluntary bodies (hospitals contributory scheme committees, approved societies and employees' associations), as well as by all groups in the medical profession, of the principles advocated in their proposals. This was carried.

Annual General Meeting.

Prof. A. H. BURGESS, the President of the Association, took the chair at the annual general meeting. In announcing that Dr. W. G. Willoughby had been elected president for the year 1931–32, he said that this was the first occasion on which a medical officer of health had been chosen for the presidency.—Dr. WILLOUGHBY said that Eastbourne was preparing an enthusiastic welcome for the Representative Body in 1932.

WORK OF THE LONDON HOSPITAL.—Last year the 13,992 in-patients (839 beds) stayed an average of 18·55 days; the 645 deaths were a percentage of 4·83. The 89,972 out-patients made 461,297 attendances. The average total cost of each in-patient was £14 4*s.* 9*d.* and of each out-patient attendance 2*s.* 7*d.* At £265,311, the expenditure left a surplus of £19,043, but this satisfactory pecuniary position was due to legacies, which produced £68,840. Whereas 20 years ago the income from investments was only £20,810, it is now £53,117.

CANCER OF THE LIP, TONGUE, AND SKIN.

A STATISTICAL INQUIRY.

STATISTICAL inquiries made by Dr. Janet Lane-Claypon into the results of treatment of cancer of the breast and the uterus have been published from time to time by the Ministry of Health. She has now made an analysis of the literature of cancer of the lip, tongue, and skin, which forms No. 59 of the valuable Reports on Public Health and Medical Subjects issued by the Ministry.[1] Earlier reports in the series on cancer have dealt mainly with the organs usually affected in women. Cancer of the lip and tongue occur mainly in men but, contrary to accepted theories, the investigation does not incriminate smoking in itself as an important causal factor, though roughness and heat of the pipe or holder may be. Owing to certain technical similarities it has been convenient also to consider cancer of the skin in this report.

In considering treatment the percentage results are mostly set out in the form of two different survival-rates, the crude and the net survival-rates, the difference being as follows :—

(*a*) The *crude* survival-rate.—This is the percentage of survivors on the total sample treated whether by surgery or radiotherapy, and whether in one stage or in various stages of the disease. This rate regards all cases not definitely known to be alive and well as having died of cancer and gives too unfavourable a result.

(*b*) The *net* survival-rate.—Experience has shown (cf. Report on Public Health and Medical Subjects, No. 47, Ministry of Health) that patients "lost sight of" are probably not all dead. The correction made by ignoring them in addition to those dying of causes other than cancer secures the nearest approach to accuracy which it seems possible to obtain.

In calculating these survival-rates no patient has been included among the living who, though alive, was known to have a recurrence of the disease.

Cancer of the Lip.

A survey of the literature on operability suggests that only 10 per cent. of the patients who apply for treatment for new growths on the lip are in an inoperable stage. In considering the figures supplied by authors writing from 1878 onwards it must be remembered that the standard of operability has changed very considerably during the period under review. The operative mortality is not serious, except in advanced cases when removal of bone is necessary. Almost all the cases reviewed have been subjected to histological examination, even as long ago as 1865. The crude survival-rate after local excision is 27·3 per cent. after five years and 55·6 per cent. after three years. The net survival-rate is 29·4 per cent. after five years and 58·4 per cent. after three years. In cases where the glands were always removed the survival-rate is 80 per cent. There were no great differences between the three-year and five-year rates, for 90 per cent. of recurrences occur within three years. The available sample for all stages of the disease and for all methods of radiotherapy gives a survival-rate of 76·1 per cent. at three years after treatment. The results of treating recurrent cases are good enough either by operation or by radiotherapy to make treatment worth undertaking.

Cancer of the lip seems to take a slow course if it is not treated, and cases are on record in which the symptoms had been present for 36 years. Most cases, however, come for treatment within one year of the onset of symptoms. The lower lip is much more often affected, the proportions of the two lips being 95 and 5 per cent. It occurs 12 to 14 times more often among men than among women, although women are more apt than men to have cancer in the upper lip. The mean age of incidence is unknown, but the average age of application at hospital is 57 years, and the average age at death is 70 years. Metastases are rare.

The statistical data which have been collected do not support the common belief that smoking has an ætiological relationship to cancer of the lip; in 184 cases investigated, roughly one-quarter were affected with cancer at the place where they held their pipes. In the Finisterre district of France, both sexes smoke the short pipe, but cancer of the lip is as rare among women there as in other parts of the world, nor does the literature suggest any other common antecedent condition. There is, however, some reason to suppose that methods of smoking likely to damage the epithelium—e.g., the old clay pipe—may act as chronic irritant agents. The commonest precursory lesions are blebs and ulcers.

Cancer of the Tongue.

Literature on cancer of the tongue was found to give unsatisfactory data for the purposes of this report, and the results are only to be considered as relatively accurate. Apparently from 20 to 25 per cent. of all patients operated on are alive and well three years later, but the true survival-rate is probably somewhat higher than this. The operative mortality rate varies from 7 to 12 per cent. The samples available suggest that radiological treatment shows a better survival-rate than operation—37·8 per cent. and 59 per cent. in a small sample from the Radium hemmet, Stockholm. Both crude and net survival rates are higher for the three-year than for the five-year period, suggesting that three years is an insufficient interval on which to base statistics. The disease, on the whole, has a short natural duration—about 16 months. Patients usually apply for treatment seven or eight months after the appearance of symptoms; the delay is all the more serious in that the disease has such a short natural period and disseminates so rapidly. It reaches the glands early in the disease, and most surgeons prefer to treat them as part of the routine.

The mean age is rather lower than for cancer of the lip: 54 years, and the mean age at death is 61. Cancer of the tongue is about ten times as common among men as among women. The commonest antecedent condition recorded is syphilis, sometimes accompanied by other forms of chronic irritation. There is also a close relationship with leucoplakia with or without previous syphilis. No accurate data of the supervention of cancer upon syphilis are, however, available. The figures, so far as they go, do not suggest an association between smoking and cancer of the tongue. While the jagged edge of a tooth seems to have been an exciting cause in a few cases, statistics dealing with dental abnormalities are too scanty to be worth consideration. Betel chewing seems to produce cancer of the mouth in some parts of the East but not in other parts, and the literature does not indicate whether the difference is due to some variety in the composition of the quid or to different habits of chewing.

Cancer of the Skin.

The samples show wide variation in survival-rates but on the whole it appears that 40 to 50 per cent.

[1] H.M. Stationery Office. 1930. Pp. 121. 2*s*.

all patients treated are alive and well three years ter operation, and there seems little doubt that lequate radiological treatment will give a figure of) to 90 per cent. Despite some difference of opinion appears that results are more favourable with basal-lled than with squamous-celled cancers. Radio-herapy seems to give good results with relapsed ases. The disease takes a long course; the average eriod between the appearance of symptoms and the pplication for treatment is ten years. Less than a uarter of the patients apply for treatment within a ear. Most of the cases occur in the upper part of he head and face, and the majority of these are of he rodent type, which invades the glands very owly if at all. A few cases of sarcoma have been navoidably included; radiotherapy seems to give ood results in sarcomata and melanotic sarcomata. en and women are affected about equally with a ight preponderance among men. Apparently the sions in women nearly all occur in the upper part f the face. The mean age varies between 55 and 58, nd the mean age of death is 66 for men and 68·7 for omen. The precursors appear in the form of blebs, usts, warts, pimples, scabs, nodules, or injuries. seems reasonably certain that a high percentage, not all cancers of the skin, develop on a previously xisting lesion and that many of them are caused by equent irritation. The relationship of occupation ith cutaneous cancer has been exhaustively investi-ated; chimney-sweeping and mule-spinning are he two occupations which show a high percentage deaths from cancer of the scrotum. There is sufficient evidence to lay much stress on the relation-ip of the disease to rigours of climate, whether cold, eat, or general exposure.

CANCER OF THE EXTERNAL GENITALIA.

Cancer of the penis and scrotum form a large part all deaths attributable to cancer of the skin. In ancer of the penis the results obtained by treatment re very satisfactory, but curiously enough no data re available from any general hospital in this country. tatistics from abroad show that the crude survival-ate after three years is 47·4 per cent. and after five ears 41·1 per cent. It is probable that the results f radiotherapy are as favourable as those of surgery, ut no large series have been published. The average eriod between the onset of symptoms and the pplication for treatment is 14 months; the interval often extended to two years by preliminary ieffective treatment at home. There seems to be a igh proportion of cases showing enlarged but not et cancerous glands. Visceral metastases are rarely ound. The mean age is between 52 and 54 years. himosis seems to be a common antecedent and enereal disease was present in 28·4 per cent. of all ases. The disease is undoubtedly less frequent mong the circumcised.

The results of local removal of cancer of the scrotum re satisfactory; no series treated by radiotherapy on record.

The only large series of cases of cancer of the ulva is that published from Radiumhemmet, where he latest method is electro-coagulation combined ith distant radium. Of 60 cases so treated, 19 were live and well three years later.

QUEEN'S INSTITUTE OF DISTRICT NURSING.—At meeting of the council recently it was reported at up to the present time over £2800 had been received s a result of the National Gardens scheme, considerably ore than had been received to the corresponding date last ear.

INTERNATIONAL CONGRESS OF MICROBIOLOGY.

(FROM A CORRESPONDENT.)

THE first of the proposed triennial congresses of the International Society of Microbiology took place in Paris from July 20th–25th, mostly at the Pasteur Institute, under the Presidency of Prof. Jules Bordet. Some 800 members attended from many countries, and most of the honoured names in bacteriology appeared on the list of those registering. Some 30 British members were present.

The main subjects set for discussion were: variation in micro-organisms, scarlet fever, neurotropic filterable viruses, undulant fever, cholera, influenza, lipoids in immunity, and blood groups; in another section immunity in plants and spirochætes were included. In addition, a number of papers on general subjects were given—in any one of five languages. No one member could attend more than a limited number of meetings; but the full papers will be published in the Proceedings of the Congress as soon as possible. It was of interest to hear various views, often plainly contradictory to each other; thus, scarlet fever was held to be due to the specific toxin of the hæmolytic streptococcus, to allergy produced by the streptococcus, to a filterable virus; post-vaccinal encephalitis was specifically due to vaccinia virus, was not specifically due to this virus; B C G was capable of becoming pathogenic and could be split into a harmless and a virulent variety, was unchangeably avirulent. Little really new work was presented, but useful reviews of existing knowledge were given, and in this way and by the personal contacts which it affords a congress of this kind serves as an exceedingly useful clearing house of information and opinions.

A. R. Dochez's successful transmission, by means of a filtrate, of the "common cold" to apes and human beings—confirmed in another American laboratory—holds high promise. This and the extraordinary increase in the antigenic efficiency of diphtheria and tetanus toxoids produced by the addition of alum, discovered by A. T. Glenny, were two new items that attracted much attention. A useful discussion on the active immunisation of human beings against diphtheria by W. H. Park, G. Ramon, A. B. Wadsworth, and others led to general agreement that toxoid has high immunising power. Members were impressed with the lamentable tale of deaths and infection amongst research workers in yellow fever and in psittacosis. The Committee discussed nomenclature at several meetings, and arrived at certain general conclusions which will presumably be further considered at the next meeting of the International Botanical Congress.

Generous hospitality was extended to the guests, the Pasteur Institute playing a leading part. The general staff work by Dr. A. Dujarric de la Rivière and Dr. Harry Plotz was excellent. The only flaws were the failure on the part of many of the speakers to keep to the time allotted to them, and of others to speak slowly and clearly. An appreciation of the international friendliness manifest at all the meetings was made by Prof. G. H. F. Nuttall in his speech at the banquet.

The next meeting will be held in Berlin in 1933, and the announcement that the popular Prof. Martin Hahn would be President, and Sir Almroth Wright President of Honour, was received with enthusiasm.

NASOPHARYNGEAL FLORA.

A BACTERIOLOGICAL STUDY.

A STUDY of the nasopharyngeal bacterial flora of a group of the Manchester population during the period July, 1925–September, 1927, was carried out in the Department of Bacteriology of the University of Manchester by R. H. Blackburn, R. B. Boston, E. St. G. Gilmore, R. Lovell, S. P. Wilson, and Mrs. M. M. Smith.[1] The work was under the direction of Prof. W. W. C. Topley, F.R.S., and the expenses of the inquiry were defrayed by a special grant from the Ministry of Health. The scope of the investigation and the methods adopted were arranged in consultation with the Ministry's bacteriological staff. Its purpose was to follow the variations in the nasopharyngeal flora of a sample of the population of a large industrial city, and to determine whether any significant relation could be detected between fluctuations in the prevalence of any of those bacterial inhabitants of the nasopharynx which are usually credited with pathogenic potentialities, and fluctuations in the prevalence of respiratory diseases. Combined bacteriological and epidemiological inquiry has made it possible to describe the seasonal incidence of certain important bacterial species and to state how this flora fluctuates with the weekly sickness and mortality returns. The results are summarised as follows :—

(1) During the period July, 1925–September, 1927, a succession of epidemiological events in Manchester was associated with a succession of changes in the bacterial flora of the nasopharynx.

A winter and spring marked by a high incidence of respiratory disease, in the absence of any influenzal epidemic, was characterised by a high frequency of hæmophilic bacilli as a group, a low frequency of indol-forming strains within that group, and a low frequency of pneumococci.

During the following summer, with its customary fall in the incidence of respiratory disease, the frequency of pneumococci and of indol-forming hæmophilic bacilli remained at a low level, and the frequency of hæmophilic bacilli, as a group, declined.
